Reichman's Emergency Medicine Procedures

NOTICE

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the editors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

Reichman's Emergency Medicine Procedures

Third Edition

Eric F. Reichman, PhD, MD, FAAEM, FACEP, NBPAS

Clinical Associate Professor of Emergency Medicine
Attending Physician, Department of Emergency Medicine
UT-Health
McGovern Medical School
University of Texas Health Science Center at Houston-Medical School
Voluntary Attending Physician, Emergency Department
Memorial Hermann Hospital-Texas Medical Center
Houston, Texas

New York Chicago San Francisco Athens London Madrid Mexico City
Milan New Delhi Singapore Sydney Toronto

*To my wife, Kristi. Thanks for your patience and help.
I appreciate your tolerance with the mess from all the papers and files and
your trips for printer paper. Thanks for your support and understanding.
Thanks to Phoebe, Joey, Ken, Russ, Rick, Kobi, and Freya
for the help and entertaining me each day.*

Contents

<i>Contributors</i>	<i>xiii</i>
<i>Preface</i>	<i>xxix</i>
<i>Acknowledgments</i>	<i>xxx</i>

SECTION 1 Introductory Chapters 1

1 Informed Consent	1
Eric Isaacs	
2 Against Medical Advice	8
Ryan P. Kirby, Jessica J. Kirby, and Richard Dean Robinson	
3 Family Presence	15
Yanina Purim-Shem-Tov and Louis G. Hondros	
4 Procedures on Recently Deceased	18
Bryan Darger and Eric Isaacs	
5 Aseptic Technique	20
John S. Rose	
6 Basic Principles of Ultrasonography	28
Basem F. Khishfe	
7 Ultrasound Assisted Procedures	41
Jehangir Meer and Brian Euerle	
8 Trauma Ultrasound: The FAST and EFAST Scans	45
Wesley Zeger	

SECTION 2 Respiratory Procedures 55

9 Essential Anatomy of the Airway	55
Divya Karjala Chakkaravarthy, Serge G. Tyler, and Isam F. Nasr	
10 Basic Airway Management	61
Christopher J. Russo	
11 Noninvasive Airway Management	72
Gennadiy G. Voronov, Tamer Elattary, and Ned F. Nasr	
12 Pharmacologic Adjuncts to Intubation	79
Ned F. Nasr, David W. Boldt, and Isam F. Nasr	
13 Endotracheal Medication Administration	92
Megan Johnson and Shoma Desai	
14 Management of the Difficult Airway	98
Konstantin Inozemtsev, Gennadiy G. Voronov, and Ned F. Nasr	
15 Obese Airway	105
Charles Boland, Piotr C. Al-Jindi, and Ned F. Nasr	
16 Rapid Sequence Intubation	111
Ned F. Nasr, Piotr C. Al-Jindi, and Isam F. Nasr	
17 Delayed Sequence Intubation	118
Kevin J. Donnelly, Gennadiy G. Voronov, and Ned F. Nasr	
18 Orotracheal Intubation	121
Hyang won Paek, Gennadiy G. Voronov, and Ned F. Nasr	

19 Confirmation of Endotracheal Intubation	139
Tarlan Hedayati	
20 Video Assisted Orotracheal Intubation Devices	147
Pholaphat Charles Inboriboon and Curtis Blake Buchanan	
21 Fiberoptic-Assisted Endotracheal Intubation Devices	163
Igor V. Kolesnikov, Gennadiy G. Voronov, and Ned F. Nasr	
22 Endotracheal Tube Intubating Introducers and Bougies	170
Marco Mikhael, Gennadiy G. Voronov, and Ned F. Nasr	
23 Digital (Tactile) Orotracheal Intubation	178
James A. Heilman, Beech S. Burns, and O. John Ma	
24 Lighted Stylet Intubation	181
Jaroslav Tymouch, Gennadiy G. Voronov, and Ned F. Nasr	
25 Supraglottic Airway Devices	187
Fred A. Severyn	
26 Laryngeal Mask Airways	193
Ned F. Nasr, Gennadiy G. Voronov, and Luis Sequera-Ramos	
27 Double Lumen Airway Tube Intubation	211
Joseph M. Weber and Katie Tataris	
28 Fiberoptic Endoscopic Intubation	217
Ruth E. Moncayo, Alia Safi, and Ned F. Nasr	
29 Nasotracheal Intubation	228
Ned F. Nasr, Abed Rahman, and Isam F. Nasr	
30 Retrograde Guidewire Intubation	236
Ned F. Nasr, Anna Tzonkov, and Gennadiy G. Voronov	
31 Percutaneous Transtracheal Jet Ventilation	240
Gennadiy G. Voronov, Tamer Elattary, and Ned F. Nasr	
32 Cricothyroidotomy	247
Charles Boland, Ned F. Nasr, and Gennadiy G. Voronov	
33 Tracheostomy	264
Eric S. Levy and Christopher J. Haines	
34 Tracheostomy Care	275
H. Gene Hern Jr and Julie K. Oliva	
35 Transtracheal Aspiration	284
Joseph A. Salomone III	
36 Ventilator Management	288
Ahmad M. Abou Leila, Abayomi E. Akintorin, and Ned F. Nasr	

SECTION 3 Cardiothoracic Procedures 301

37 Cardiac Ultrasound	301
Basem F. Khishfe	
38 Chemical Cardioversion	313
Paul Casey and Thomas Alcorn	

39	Automated External Defibrillation	319
	James Montoya and Molly Garcia	
40	Cardioversion and Defibrillation	324
	Chirag N. Shah, Patrick J. Rogers, and Daniel S. Morrison	
41	Transcutaneous Cardiac Pacing	330
	Chirag N. Shah, Patrick J. Rogers, and Daniel S. Morrison	
42	Transthoracic Cardiac Pacing	336
	Chirag N. Shah, Guillermo Ortega, and Daniel S. Morrison	
43	Transvenous Cardiac Pacing	339
	Myles C. McClelland, Thuy Tran T. Nguyen, and Alfred Coats III	
44	Transesophageal Cardiac Pacing	348
	John Bass and Chad Gorbalkin	
45	Pacemaker Assessment	353
	Elizabeth Kwan	
46	Automatic Implantable Cardioverter-Defibrillator Assessment	373
	Carlos J. Roldan	
47	Left Ventricular Assist Device (LVAD) Assessment	384
	Paulino A. Alvarez, Myles C. McClelland, and Ashrith Guha	
48	Pericardiocentesis	394
	Marianne Juarez and Jacqueline Nemer	
49	Intracardiac Injection	408
	Tiffany Abramson and Shoma Desai	
50	Needle Thoracostomy	410
	Michael Gottlieb	
51	Tube Thoracostomy	417
	Kimberly T. Joseph and John C. Kubasiak	
52	Thoracentesis	429
	Marianne Juarez and Jacqueline Nemer	
53	Open Chest Wound Management	447
	Eric F. Reichman	
54	Emergency Department Thoracotomy	452
	Kenny Banh	
55	Open Cardiac Massage	458
	Eric F. Reichman	
56	Cardiac Wound Repair	461
	Eric F. Reichman	
57	Hilum and Great Vessel Wound Management	468
	Eric F. Reichman	
58	Thoracic Aortic Occlusion	471
	Eric F. Reichman	

SECTION 4 Vascular Procedures 475

59	General Principles of Intravenous Access	475
	Daniel Belmont	
60	Heel Stick Blood Sampling	492
	Kimberly Lynn Fugok and Christopher J. Russo	
61	Venipuncture and Peripheral Intravenous Access	495
	Daniel Belmont	
62	Peripheral Inserted Central Catheter (PICC) Lines	508
	Elizabeth Barrall Werley	

63	Central Venous Access	516
	Arun Nagdev, Craig Sisson, Benjamin Thomas, and Peter C. Wroe	
64	Ultrasound-Guided Vascular Access	541
	Srikar Adhikari and Lori Stolz	
65	Troubleshooting Indwelling Central Venous Lines	559
	James J. McCarthy	
66	Accessing Indwelling Central Venous Lines	563
	John Cruz and Chad Gorbalkin	
67	Pulmonary Artery (Swan-Ganz) Catheterization	570
	J. Elizabeth Neuman and Jessica Mann	
68	Noninvasive and Minimally Invasive Cardiac Output Monitoring	577
	Caleb P. Canders, Daniel W. Weingrow, and Alan T. Chiem	
69	Peripheral Venous Cutdown	586
	Jason M. Rotoli and Flavia Nobay	
70	Intraosseous Infusion	599
	Beech S. Burns, James A. Heilman, and O. John Ma	
71	Umbilical Vessel Catheterization	615
	Jeanne A. Noble	
72	Arterial Puncture and Cannulation	623
	Justin Grisham and Jennifer L'Hommedieu Stankus	
73	Extracorporeal Membrane Oxygenation	635
	Jean W. Hoffman and Jordan R. H. Hoffman	
74	Catheter-Based Hemorrhage Control	646
	Matthew Rosen and Andrew Grock	

SECTION 5 Gastrointestinal Procedures 657

75	Nasogastric Intubation	657
	Alex Koo and Ryan Walsh	
76	Activated Charcoal Administration	665
	Jenny J. Lu	
77	Gastric Lavage	669
	Jenny J. Lu and Rosaura Fernandez	
78	Whole Bowel Irrigation	673
	Henry D. Swoboda and Steven E. Aks	
79	Video Capsule Endoscopy for Gastrointestinal Bleeding	676
	Eric S. Levy, Christopher J. Haines, and Grant Wei	
80	Esophageal Foreign Body Removal	684
	Bashar M. Attar	
81	Balloon Tamponade of Gastrointestinal Bleeding	696
	Bashar M. Attar	
82	Gastrostomy Tube Complications and Replacement	706
	Erika Flores Uribe and Erick A. Eiting	
83	Paracentesis	717
	Alex Koo and Ryan Walsh	
84	Diagnostic Peritoneal Lavage	729
	Leann Mainis and René Ramirez	
85	Anal Fissure Management	738
	Eric F. Reichman	
86	External Hemorrhoid Management	744
	Katherine Holmes, Michael Balkin, and Hao Wang	

87	Prolapsed Rectum Reduction	748	110	Knee Joint Dislocation Reduction	928
	Jamil D. Bayram and Eric F. Reichman			Michael Gottlieb	
88	Anoscopy	752	111	Ankle Joint Dislocation Reduction	933
	Charles Huggins, Claudia Kim, and Hao Wang			Crystal Ives Tallman	
89	Rigid Rectosigmoidoscopy	757	112	Common Fracture Reduction	938
	Hao Wang, Nicole Remish, and Nestor Zenarosa			Christopher A. Gee	
90	Rectal Foreign Body Extraction	762	113	Casts and Splints	951
	Chad Holmes, Jon Wolfshohl, and Hao Wang			Eric F. Reichman	
91	Proctodysis	769			
	Hao Wang, Tyson Jay Higgins, and Richard Dean Robinson				
SECTION 6 Orthopedic and Musculoskeletal Procedures			SECTION 7 Skin and Soft Tissue Procedures		
		775			971
92	Bursitis and Tendonitis Therapy	775	114	General Principles of Wound Management	971
	Dedra R. Tolson, Brandon M. Fetterolf, and Elaine H. Situ-LaCasse			Ivette Motola and John E. Sullivan	
93	Compartment Pressure Measurement	788	115	Burn Wound Management	988
	Danielle D. Campagne and Scott T. Owens			Stephen Sandelich and Christopher J. Russo	
94	Fasciotomy	797	116	Basic Wound Closure Techniques	994
	Andrew Rotando and Justin Mazzillo			Eric F. Reichman	
95	Field Amputation of the Extremity	808	117	Tissue Adhesives for Wound Repair	1018
	Joshua T. Bucher and Michael S. Westrol			Hagop M. Afarian	
96	Extensor Tendon Repair	813	118	Advanced Wound Closure Techniques	1025
	JoAnna Leuck and Keegan Bradley			Eric F. Reichman	
97	Arthrocentesis	819	119	Management of Specific Soft Tissue Injuries	1034
	Eric F. Reichman, John Larkin, and Brian Euerle			Thomas M. Kennedy and Christopher J. Russo	
98	Methylene Blue Joint Injection	842	120	Subcutaneous Foreign Body Identification and Removal	1049
	Pholaphat Charles Inboriboon and Katherine Gloor Willet			David Murray, Laura Chun, and Dhara Patel Amin	
99	Basic Principles of Fracture and Joint Reductions	848	121	Ultrasound-Guided Foreign Body Identification and Removal	1060
	Scott C. Sherman and John Robert Hardwick			Daniel S. Morrison and Chirag N. Shah	
100	Ultrasound for Fracture and Dislocation Identification and Management	852	122	Hair Tourniquet Management	1066
	Adrian H. Flores			Asim A. Abbasi	
101	Sternoclavicular Joint Dislocation Reduction	864	123	Tick Removal	1069
	Michael D. Burg			Laurie Krass and Dhara Patel Amin	
102	Shoulder Joint Dislocation Reduction	871	124	Fishhook Removal	1073
	Damali N. Nakitende, Tina Sundaram, and Michael Gottlieb			Eric F. Reichman	
103	Elbow Joint Dislocation Reduction	895	125	TASER Probe Removal	1076
	Angelique Campen			Myles C. McClelland, Alfred Coats III, and Thuy Tran T. Nguyen	
104	Radial Head Subluxation (Nursemaid's Elbow) Reduction	900	126	Ring Removal	1080
	Mark P. Kling			Abraham Berhane, Abdoulie Njie, Robert Needleman, and Steven H. Bowman	
105	Carpometacarpal Dislocation Reduction	904	127	Subungual Hematoma Evacuation	1088
	Rene Carizey and Priya D. Perumalsamy			Steven H. Bowman, Neera Khattar, and Natasha Thomas	
106	Metacarpophalangeal Joint Dislocation Reduction	908	128	Subungual Foreign Body Removal	1094
	Michael Gottlieb			Ginger Clinton, Ameera Haamid, and Steven H. Bowman	
107	Interphalangeal Joint Dislocation Reduction	914	129	Nail Bed Repair	1097
	Michael Gottlieb			Dayle Davenport	
108	Hip Joint Dislocation Reduction	919	130	Ganglion Cyst Aspiration and Injection	1105
	Michael Gottlieb			Thomas P. Graham	
109	Patellar Dislocation Reduction	925	131	Subcutaneous Abscess Incision and Drainage	1108
	Mark P. Kling			Priya D. Perumalsamy	
			132	Paronychia or Eponychia Incision and Drainage	1119
				Lisa Palivos and Tim Richardson	

133	Felon Incision and Drainage	1123
	Lisa Palivos and Sonali Gandhi	
134	Pilonidal Abscess or Cyst Incision and Drainage	1126
	Carolyn Chooljian	
135	Perianal Abscess Incision and Drainage	1130
	John Ramos and Deena Ibrahim Bengiamin	
136	Sebaceous Cyst Incision and Drainage	1137
	Carlos J. Roldan	
137	Hemorrhage Control	1141
	Christopher Freeman and Ariana Wilkinson	
138	Trigger Point Injections	1154
	Danielle D. Campagne	
139	Escharotomy	1159
	Michael A. Schindlbeck and Carlos E. Brown, Jr.	
140	Subcutaneous Hydration (Hypodermoclysis)	1163
	Mary J. O	
141	Subcutaneous Extravasation and Infiltration Management	1168
	Henry D. Swoboda	

SECTION 8 Neurologic and Neurosurgical Procedures 1175

142	Lumbar Puncture	1175
	Damali N. Nakitende, Michael Gottlieb, and Tina Sundaram	
143	Blood Patching for Postdural Puncture (Lumbar Puncture) Headache	1195
	Gunnar Subieta-Benito, Maria L. Torres, and Ned F. Nasr	
144	Burr Holes	1200
	Caleb P. Canders, Noah T. Sugerman, and Amir A. Rouhani	
145	Lateral Cervical Puncture	1207
	Eric F. Reichman	
146	Intracranial Pressure Monitoring	1210
	Hannah Kirsch, Shahed Toossi, and Debbie Yi Madhok	
147	Ventriculostomy	1217
	John Burke, Shahed Toossi, and Debbie Yi Madhok	
148	Ventricular Shunt Evaluation and Aspiration	1223
	Daniel W. Weingrow and Jacob Lentz	
149	Subdural Hematoma Aspiration in the Infant	1231
	Sarah J. Christian-Kopp	
150	Skeletal Traction (Gardner-Wells Tongs) for Cervical Spine Dislocations and Fractures	1236
	Thomas W. Engel and Rebecca R. Roberts	
151	Reflex Eye Movements (Caloric Testing and Doll's Eyes)	1241
	Atilla Üner	
152	Myasthenia Gravis Testing	1245
	Eric F. Reichman	

SECTION 9 Anesthesia and Analgesia 1249

153	Local Anesthesia	1249
	Mark Supino and Daniel Yousef	

154	Topical and Noninvasive Anesthesia	1257
	Sonali Gandhi and Michael A. Schindlbeck	
155	Hematoma Blocks	1267
	Thomas P. Graham	
156	Regional Nerve Blocks (Regional Anesthesia)	1271
	Eric F. Reichman and Jehangir Meer	
157	Intravenous Regional Anesthesia	1312
	Christopher Freeman and Emily Cooper	
158	Nitrous Oxide Analgesia	1320
	René Ramirez and Leann Mainis	
159	Procedural Sedation and Analgesia (Conscious Sedation)	1328
	Hagop M. Afarian	

SECTION 10 Obstetrical and Gynecologic Procedures 1347

160	Ultrasound in Early Pregnancy	1347
	Srikar Adhikari, Wesley Zeger, and Lori Stolz	
161	Uterine Bleeding	1363
	Leah W. Antoniewicz, Beth R. Davis, Kara N. Purdy, Alexis R. Taylor, Lindsay K. Grubish, and Sarah J. Christian-Kopp	
162	Normal Spontaneous Vaginal Delivery	1371
	Stephen N. Dunay and Simeon W. Ashworth	
163	Episiotomy	1384
	Francisco Orejuela and Padraic Chisholm	
164	Shoulder Dystocia Management	1393
	Christopher Freeman and Adi Abramovici	
165	Breech Delivery	1401
	Sarah J. Christian-Kopp	
166	Postpartum Hemorrhage Management	1409
	Leah W. Antoniewicz	
167	Perimortem Cesarean Section (Perimortem Cesarean Delivery)	1418
	Jeanne A. Noble	
168	Symphysiotomy	1424
	Ikem Ajalo	
169	Bartholin Gland Abscess or Cyst Incision and Drainage	1427
	Alison Uyemura and Charlie C. Kilpatrick	
170	Sexual Assault Examination	1433
	Monique A. Mayo and Christopher J. Russo	
171	Culdocentesis	1445
	JoAnna Leuck and Jennalee Cizenski	
172	Prolapsed Uterus Reduction	1449
	Andrea Dreyfuss and Eric R. Snoey	

SECTION 11 Genitourinary Procedures 1455

173	Urethral Catheterization	1455
	Richard Dean Robinson and Caleb Andrew Rees	
174	Suprapubic Bladder Aspiration	1466
	Richard Dean Robinson, Teresa Proietti, and Andrew Shedd	
175	Suprapubic Bladder Catheterization (Percutaneous Cystotomy)	1473
	Richard Dean Robinson, Aaron W. Bull, and Andrew Shedd	

176	Retrograde Urethrography and Cystography	1481	199	Tympanocentesis	1622
	Richard Dean Robinson and Sasha Michael Dib			Paul J. Jones	
177	Anesthesia of the Penis, Testicle, and Epididymis	1487	200	Auricular Hematoma Evacuation	1625
	Eric F. Reichman			Eric F. Reichman	
178	Priapism Management	1493	201	Nasal Medication Administration	1633
	Steven Go			Crystal Ives Tallman and Joel Tallman	
179	Paraphimosis Reduction	1500	202	Nasal Foreign Body Removal	1637
	Matthew D. Schwartz and Ann P. Nguyen			G. Carolyn Clayton, Katarzyna M. Gore, and Melissa M. Rice	
180	Phimosis Reduction	1506	203	Nasal Fracture Reduction	1646
	Kevin O'Rourke			Eric F. Reichman	
181	Dorsal Slit of the Foreskin	1510	204	Nasal Septal Hematoma Evacuation	1655
	Carlos J. Roldan			Michael Friedman and Jessica Tang	
182	Manual Testicular Detorsion	1514	205	Epistaxis Management	1660
	Steven Go			Steven Lai and Matthew Waxman	
183	Zipper Injury Management	1519	206	Laryngoscopy	1676
	Anthony W. Catalano and Ricky N. Amii			Steven J. Charous	
184	Genitourinary Foreign Body Removal	1523	207	Airway Foreign Body Removal	1683
	Dennis Hsieh, Claire H. Lyons, and Karen Lind			Guy Shochat, Jacqueline Nemer, David L. Walner, and Martin E. Anderson, Jr.	
	SECTION 12 Ophthalmologic Procedures	1535	208	Peritonsillar Abscess Incision and Drainage	1690
185	Eye Examination	1535		Daniel S. Morrison and Chirag N. Shah	
	Shari Schabowski and Carmen Alcala			SECTION 14 Dental Procedures	1699
186	Contact Lens Removal	1556	209	Dental Anesthesia and Analgesia	1699
	Scott A. Heinrich and Dino P. Rumoro			Eric F. Reichman	
187	Ocular Burn Management and Eye Irrigation	1560	210	Dental Abscess Incision and Drainage	1711
	Steven J. Socransky			Richard Dean Robinson and Peter S. Kim	
188	Intraocular Pressure Measurement (Tonometry)	1567	211	Post-Extraction Pain and Dry Socket (Alveolar Osteitis) Management	1718
	Rosalia Njeri Mbugua and Adam Jennings			Eric F. Reichman	
189	Digital Globe Massage	1576	212	Post-Extraction Bleeding Management	1720
	Carlos J. Roldan and Eric F. Reichman			Eric F. Reichman	
190	Anterior Chamber Paracentesis	1579	213	Defective Dental Restoration Management	1724
	Rene Carizey			Richard Dean Robinson and Daisha McLarty	
191	Corneal Foreign Body Removal	1582	214	Subluxed and Avulsed Tooth Management	1728
	Scott A. Heinrich and Dino P. Rumoro			Richard Dean Robinson, Adam Flink, and Ryan Nathaniel Krech	
192	Corneal Rust Ring Removal	1588	215	Fractured Tooth Management	1736
	Adam Jennings, Marcus Holmes, and Devin Sandlin			Richard Dean Robinson, Mahmuda Farha, and Bharti R. Chaudhari	
193	Eye Patching and Eye Shields	1591	216	Temporomandibular Joint Dislocation Reduction	1740
	Teresa D. Le and Adam Jennings			Marilyn M. Hallock	
194	Acute Orbital Compartment Syndrome (Retrobulbar Hemorrhage) Management	1595	217	Arch Bar Separation	1747
	Andrew F. Perin, Jamil D. Bayram, and Sami H. Uwaydat			Richard Dean Robinson, Amanda Pientka, and Phuc Ba Duong	
195	Globe Luxation Reduction	1600		SECTION 15 Podiatric Procedures	1751
	Briana D. Mazur, Adam Jennings, and Heidi Knowles		218	Ingrown Toenail Management	1751
196	Hordeolum (Stye) Incision and Drainage	1603		Sean Dyer and Jeffrey Schaidler	
	Sami H. Uwaydat, Andrew F. Perin, and Jamil D. Bayram		219	Plantar Puncture Wound Management	1755
	SECTION 13 Otolaryngologic Procedures	1607		Vishal Bhuvra and Dhara Patel Amin	
197	External Auditory Canal Foreign Body Removal	1607	220	Toe Fracture Management	1760
	G. Carolyn Clayton, Katarzyna M. Gore, and Melissa M. Rice			JoAnna Leuck and Tyler Hedman	
198	Cerumen Impaction Removal	1616			
	Dayle Davenport				

221	Plantar Wart Management	1764	227	Hyperthermic Patient Management	1821
	Kevin O'Rourke			Jessica Mann and J. Elizabeth Neuman	
222	Neuroma Management.	1769	228	Autotransfusion.	1828
	Justin C. Bosley and Eric R. Snoey			Carlos J. Roldan and Amit Mehta	
223	Management of Select Podiatric Conditions	1775	229	Helmet Removal	1833
	JoAnna Leuck, Jacob Hurst, and Anant Patel			Ashley N. Sanello and Atilla Üner	
	SECTION 16 Miscellaneous Procedures	1789	230	Pneumatic Antishock Garment (MAST Trousers)	1841
224	Relief of Choking and Acute Upper Airway Foreign Body Removal	1789		Evan J. Weiner	
	Guy Shochat and Jacqueline Nemer		231	Hazmat Patient Management	1845
225	Induction of Therapeutic Hypothermia (Targeted Temperature Management)	1797		Atilla Üner

John Peter Smith Health Network
Fort Worth, Texas

Preface

Emergency Medicine is extremely broad and the advances have been amazing in recent years. The field covers the neonate through the geriatric, surgical and medical, and encompasses all organ systems. Emergency Medicine is rapidly evolving. Procedural skills must supplement our cognitive skills. Achieving proficiency in procedural skills is essential for the daily practice of Emergency Medicine. We have produced a clear, complete, and easy to understand textbook of Emergency Medicine procedures. This new edition addresses the diverse topic of Emergency Medicine. This text will provide medical students, residents, advanced practice practitioners, and the seasoned Emergentologist with a single procedural reference on which to base clinical practices and technical skills.

The primary purpose of this text is to provide a detailed and step-by-step approach to procedures performed in the Emergency Department. It is expressly about procedures. It is not meant to be a comprehensive reference but an easy to use and clinically useful procedure book that should be in every Emergency Department. The contents and information are complete. It is organized and written for ease of access and usability. The detail is sufficient to allow the reader to gain a thorough understanding of each procedure. When available, alternative techniques or hints are presented. Each chapter provides the reader with clear and specific guidelines for performing the procedure. Although some may use this text as a library reference, its real place is in the Emergency Department where the procedures are performed. Despite its size, I hope that this book will find its way to the bedside to be used by medical students, residents, advanced practice providers, and practicing clinicians.

This book will satisfy the needs of a variety of backgrounds and training. While this text is primarily written for Emergentologists, many other practitioners will find this a valuable reference. This book is written for those who care for people with acute illness or injury. Medical students and residents will find this an authoritative work on procedural skills. Medical students, residents, nurse practitioners, physician's assistants, and practitioners with limited experiences will find all the information in each chapter to learn the complete procedure. Family Physicians, Internists, and Pediatricians will find this text useful to review procedures infrequently performed in the clinic, office, or urgent care center. Intensivists and Surgeons involved in the care of acutely ill patients will also find this book a wonderful resource. The experienced clinician can get a quick refresher on the procedure while enhancing their knowledge and skills. Physicians actively involved in education will find this text an easy to understand and well-illustrated source of didactic material.

The book is organized into sections with each representing an organ system, an area of the body, or a surgical specialty. Each chapter, with a few exceptions, is devoted to a procedure. This should allow quick access to complete information. The chapters have a similar format to allow information to be retrieved as quickly and as efficiently as possible. There are often several acceptable methods

to perform a procedure. While alternative techniques are described in many chapters, we have not exhaustively included all alternative techniques. Key information, cautions, and important facts are highlighted throughout the text in bold type.

Each chapter, with a few exceptions, has a standard format. The relevant anatomy and pathophysiology is discussed followed by the indications and contraindications for the procedure. A list is provided of the necessary equipment. The patient preparation including consent, anesthesia, and analgesia is addressed. The procedure is then described in a step-by-step format. Cautions are placed where problems commonly occur. Alternative techniques and helpful hints for each procedure are presented. The aftercare and follow-up are discussed. Any potential complications are described including the methods to reduce and care for the complications. Finally, a summary contains a review of any critical or important information.

This book covers a wide variety of procedures that may be performed in a rural or urban Emergency Department. This includes procedures performed routinely or rarely; procedures that are often performed in the acute care, clinic, and office settings; procedures that are performed frequently in the daily practice of Emergency Medicine; and procedures that are seldom to rarely performed but critical to the practice of Emergency Medicine. Some procedures are uncommon, may not be known to the reader, and provide an opportunity to acquire new information that may be converted with proper practice and training into a useful skill. A few of the procedures are performed only by Surgeons and are included to promote understanding when the patient presents to the Emergency Department with a complication. This new edition has added chapters, algorithms, clinical pictures, cutting-edge technological advancements, radiographs, and tables based upon readers' comments, input, and suggestions.

We have drawn on a wide variety of authors. The majority of authors are residency-trained, board-certified, and practicing Emergentologists. We have the honor of having some contributors from outside the field of Emergency Medicine and who are experts in their own specialty. All authors do have biases because of differences in education, experience, and training. We have tried to base all recommendations on sound clinical and scientific data. However, we have not excluded personal experience or preferences when appropriate. In these cases, the authors also present alternative techniques.

This book has grown and changed with this third edition. I am happy and privileged to edit this third edition of the text. Continued input and suggestions from you, the reader, would be most appreciated. Let me know what additional procedures should be included or excluded in the future. Any errors, in the end, are mine. Please let me know of any mistakes or omissions, big or small, at eric.f.reichman@gmail.com.

Eric F. Reichman, PhD, MD

Acknowledgments

I must thank my wife Kristi for all of her patience during this endeavor that took many hours. Phoebe, Joey, Kobi, and Freya always kept me entertained, day and night. Thanks to Ken and Russ for all the support and help.

I would like to acknowledge the support of friends, colleagues, current residents, and former residents in the Departments of Emergency Medicine at The University of Texas at Houston Medical School and Cook County Hospital. They provided friendship and encouragement and were always there when needed. A special thanks always goes to Bob Simon, MD and Jeff Schaidler, MD who got me started and set me on this academic path.

The support from Janet Sherry, Yolanda Torres, and Jamie McCarthy, MD was invaluable.

I want to thank all the authors. Many of you are good friends that I cherish, and all of you gave of yourselves and your time.

Susan Gilbert is a wonderful medical illustrator and friend. Her input and assistance only added to the illustrations of the editions of this book. Working with her was easy, fun, and simple.

Thanks to all those at McGraw-Hill Education, especially Kim Davis and Amanda Fielding. The tracking of the chapters, communication, and assistance when needed made this edition easier to complete than previous editions.

Eric F. Reichman, PhD, MD

Introductory Chapters

1

Informed Consent

Eric Isaacs

This chapter is designed as a practical reference for the Emergency Physician (EP). It focuses on the unique challenges of informed consent in the Emergency Department (ED). It presents a practical guide for the informed consent process, reviews the exceptions, and offers suggestions on difficult scenarios of informed consent in the ED.

INFORMED CONSENT

The right of a patient to make decisions about their body, including the refusal of recommended procedures and treatment, is an important concept in medical practice with foundations in law and medical ethics. **Informed consent is the process of communication that demonstrates respect for a patient's right to make autonomous decisions about their health care. Informed consent is an ethical practice and a legal requirement for all procedures and treatments.**¹

UNIQUE CHALLENGES OF INFORMED CONSENT IN THE ED

Each practice environment presents its own challenges to the process of obtaining informed consent. **Physicians frequently fail to fulfill all the requirements of obtaining informed consent.**²⁻⁴ The ED presents significant challenges, which despite assumptions to the contrary, results in a greater need to spend time delivering information and engaging patients in their care decisions to the extent possible (Table 1-1). Time pressure and acuity are the most critical factors that influence the care paradigm in the ED. Care provided in the ED spans the full continuum of care as nonacute care is increasingly sought in the ED. Care in the ED addresses the full spectrum of society with patients from diverse health literacy, language origins, socioeconomic backgrounds, and recognized vulnerable populations (e.g., children, elderly, and prisoners). EPs need to be prepared to address the broad clinical needs of diverse patients under pressure without the traditional physician–patient relationship. Systemic constraints exacerbate this challenged professional context as patients have no choice in the treating physician or the treating facility. The location to transport the patient is often dictated by prehospital protocols. Tension may arise when a patient's wishes conflict with greater societal or institutional needs

TABLE 1-1 Challenges for the EP to Spend Time Engaged in Conversation with a Patient

Lack of facility choice
Little privacy
No prior relationship
Pace of care challenges lay person decisions
Public health or system-imposed constraints
Time pressure

for efficiency and protocol compliance independent of the patient's preferences and needs. Examples include a trauma activation or a public health emergency. Increasing space constraints and crowding found in most EDs create a lack of privacy that can impede the free exchange of sensitive information. Procedural interventions in the ED are often concurrently diagnostic and therapeutic, further complicating informed decisions.

The torrent of complex medical information physicians provide patients is overwhelming in the most controlled settings. It is only made worse in the high-emotion and high-stress environment of the ED. EPs often make rapid decisions with limited information. Many of our colleagues in other specialties may not share this skill. The EP's expectations of patients must be equally, if not more, tolerant. The absence of an ongoing physician–patient relationship offers no basis upon which to build trust, elicit values, and draw preference knowledge. Lack of a prior relationship tests the ability to establish an immediate rapport with patients and renders patients' ability to express their values most important.

There may not be time to ponder the intricacies of medical ethics in the ED or to satisfy all the requirements of searching for the best surrogate decision maker when there is uncertainty about a patient's preferences or a potential refusal. Many EPs will default to doing as much as possible in these difficult situations.⁵ There is often enough time to make a considered decision before acting in the most aggressive fashion. While some say that it is easier to withdraw care once the clinical picture becomes clearer, this aggressive course of action must be balanced with the knowledge that EP may be performing a painful or unwanted procedure on a patient who has previously made their wishes clear. Informed consent was often bypassed in the past under the presumption that a patient would want aggressive treatment. The scope of ED care and societal norms have shifted in recent years. **Informed consent for procedures in the ED needs to reflect the current standards of practice.**

LEGAL FOUNDATION FOR INFORMED CONSENT

Consent originates in the legal doctrine of battery (i.e., touching of the body without permission). The notion of protecting a patient from the bodily trespass of a procedural invasion was framed by Justice Cardozo in 1914: "[e]very human being of adult years and sound mind has a right to determine what shall be done with his own body; and a surgeon who performs an operation without his patient's consent commits an assault, for which he is liable in damages...."⁶ By 1957, the notion of consent shifted from mere permission to an authorization following "the full disclosure of facts necessary to an informed consent."⁷ Emerging at the same time as the bioethics movement's shift away from paternalistic medicine toward a patient's rights focus in medicine was *Cantebury v. Spence*.⁸ **This case resulted in an appeals court establishing a physician's duty to disclose the risks and benefits of a procedure and its alternatives and introduced the reasonable patient standard. The reasonable patient standard is what a reasonable patient would need to know to make an informed choice, shifting away from the professional standard, what most physicians deemed necessary.** The standard for disclosure today varies by state.⁹ As a result of the informed

consent “duty,” the legal and risk management function of informed consent (i.e., consent process that meets institutional and/or legal parameters for formal recognition, referred to as “effective consent”) overshadows the ethically driven process of informed consent (i.e., consent as a communication process that demonstrates respect for a patient’s autonomy, referred to as “autonomous authorization”). These two aspects serve distinct functions that are often conflated under “informed consent.” Both are necessary for valid informed consent and are addressed separately throughout this chapter.¹⁰

The exception presuming permission to treat in an emergency has equally deep roots. Justice Cardozo’s opinion continues, “[t]his is true except in cases of emergency where the patient is unconscious and where it is necessary to operate before consent can be obtained.”⁶ In *Canterbury v. Spence*, “the emergency exception” is included as a privilege from the duty to disclose when “the patient is unconscious or otherwise incapable of consenting, and harm from a failure to treat is imminent and outweighs any harm threatened by the proposed treatments.” It also states that a “physician should, as current law dictates, attempt to secure a relative’s consent if possible.” **In the emergency context, one may presume permission: (1) to do what is necessary when (a) there is imminent harm from nontreatment and (b) when harm from nontreatment outweighs the harm from the proposed intervention; (2) where the patient is unconscious or unable to participate in care decisions; and (3) when the patient’s preferences are not known and no surrogate is immediately available to provide authorization.**¹¹

ETHICAL FOUNDATION FOR INFORMED CONSENT

In an era of patients’ rights and shared decision-making, robust informed consent reflects a process of communication that secures that a patient “gives an informed consent to an intervention if (and perhaps only if) one is competent to act, receives a thorough disclosure, comprehends the disclosure, acts voluntarily, and consents to the intervention.”⁹

It is not uncommon to encounter the challenge of a patient refusing a recommended procedure or intervention in a health care environment where there is an expectation for more active patient participation in health care decisions. Central to a strong patient–physician relationship is the desire to promote patient well-being and simultaneously respect patient autonomy. Conflict between EPs and patients may arise when views of what is in a patient’s best interest differ between them. EPs with the greatest integrity come to work with the intention to act in the best interests of patients, and do so with a focus on the prevention and eradication of disease to preserve life and improve disability. **The patient may consent or refuse the recommendation after an EP has fully informed a capable patient about an intervention in an understandable way. An initial refusal of recommended treatment should begin a critical conversation that confirms all the elements of an informed refusal. The informed refusal process will respect patient autonomy by accepting a patient’s view of well-being and may require honoring a refusal of the recommendation.**¹²

EP’S ROLE AND GOALS IN INFORMED CONSENT

The EP’s role in the informed consent process is to provide patients the information needed to make their own decisions. Provide written sheets that cover all aspects of the procedure if available. It is important not to overwhelm a patient with too much information or complex clinical decisions. **Including patients in appropriate care decisions (e.g., the informed consent process for a procedural intervention) is an ethically important goal.**

TABLE 1-2 The Goals of EPs in the Informed Consent Process

Allow autonomous authorization (patient may consent or refuse)
Give information (more than we think we need to give)
Make information accessible
Offer guidance in weighing information
Support patients to make their own decision

EPs must pay attention to the informed consent process to accomplish the goal of respect for autonomy (Table 1-2). EPs need to provide more information to the patient than they think is needed. Research indicates that patients need more information than physicians think they need to feel “informed” in the decision-making process.¹³ The need for a procedure seems obvious to the EP, and the balance of the considerations clearly tips in the favor of “do it.” EPs must slow down to fully explain the rationale for their recommendation with patients and to offer patients information that allows their meaningful consideration of the recommendation so that they can reach their own decisions. A good guideline is to offer more time and information for procedures carrying greater risk.¹⁴ **EPs must make the effort to work against the features of the ED (Table 1-1 and presumption of consent). Allow patients capable of engaging in their care decisions to express autonomous authorization.** This is achieved by giving patients sufficient information, in an understandable way, and by honoring their decisions.

COMPONENTS OF THE INFORMED CONSENT AND INFORMED REFUSAL PROCESS

Informed consent is the communication process that demonstrates and protects a patient’s self-determination by providing a patient with decision-making capacity with sufficient, understandable information and allows the patient to make a voluntary, knowledgeable decision. There are five requirements that must be satisfied.⁹ These include the patient having decision-making capacity, the EP providing sufficient information, the patient understanding the information, the patient giving consent in a voluntary fashion without coercion, and the patient communicating their decision (Table 1-3).

DECISION-MAKING CAPACITY

The terms “competence” and “decision-making capacity” are frequently used interchangeably, but their strict meanings are different. **Competence is a legal term with broader applications related to financial matters and the determination of personal choices. Decision-making capacity is a clinical term that speaks to the specific capacity to make a clinical decision.** Many people who are legally “incompetent” retain health care decision-making capacity. **If the patient does not have decision-making capacity, informed consent cannot be obtained and it must be obtained from a surrogate decision maker, or the patient may fall into an exception from informed consent.**

TABLE 1-3 Requirements of the Informed Consent Process⁹

1. Does the patient have the decision-making capacity to make this decision?
2. Has there been disclosure of relevant procedural information (including risks/benefits for intervention, alternatives, and nonintervention)?
3. Has the information been presented in a way that is understandable to the patient?
4. Has the information been presented in a way that allows the patient to make their own decision voluntarily while still being informed of the physician’s recommendation?
5. Has the patient communicated a decision?
6. Does an exception apply?

DETERMINING DECISION-MAKING CAPACITY

The determination that a patient has decision-making capacity is at the core of informed consent. By default, EPs assume that a patient has capacity and confirm this through routine dialogue with the individual. Confirm six elements when there is a question about a patient's capacity to make an informed decision about procedures or treatment.¹⁵ The patient must be able to: understand and process the options, weight the benefits and risks, apply a set of values and goals to the decision, arrive at a decision, communicate a choice, and demonstrate capacity to make the decision (Table 1-4).

Determination of capacity is a clinical decision based on the judgment of the EP regarding the patient's actual level of functioning and appreciation of the ramifications of the clinical situation.¹⁶ The degree of capacity needed to understand risks and benefits of suturing a finger laceration differs from a cardiac catheterization. A patient may be able to understand one choice but not another. An Alzheimer patient who is pleasant, oriented to place, and oriented to year may be unable to appreciate the consequences of a decision. This patient may have capacity for some tasks but may lack the capacity to consent for a specific procedure (e.g., lumbar puncture).

The EP needs to assess the ability for the individual to weigh the risks considering their (i.e., the patient's) own values. An example would be the ramifications of a fracture reduction on the dominant hand. A construction worker or musician may decide different than an individual whose livelihood does not depend on perfect hand function.

A recognized element of decision-making capacity is whether the patient's decision is consistent over time. This is not necessarily applicable specifically to the ED. A possible heuristic is whether the decision is consistent with the person's narrative and values as expressed consistently over time in life choices. The decision-specific nature of capacity acknowledges that the level of capacity needed depends upon the complexity of the decision, with greater capacity needed for decisions with graver consequences. **The degree of capacity needed to consent does not necessarily equal the degree of capacity needed to refuse a recommended intervention.**¹² Informed refusal will be discussed later in this chapter.

Decision-making capacity is a dynamic process and changes depending upon the patient's evolving condition and task in question. The ED patient may be able to participate to a greater or lesser extent depending on fluctuations in their condition and alterations of their sensorium from the administration of medications. Make efforts whenever possible to enhance the patient's decision-making capacity (e.g., reduce pain medication temporarily or visit patients at optimal times) to engage them to the fullest extent possible in their care.

Emancipated minor and adolescent laws vary from state to state.⁹ **Emancipated minors are legally recognized as adults and responsible for their own finances and care.** They can provide fully informed consent. Know the local laws where minors who are not emancipated may give consent for sensitive conditions or procedures (e.g., those of a reproductive nature or substance abuse).

Informed consent may not be possible with some populations (e.g., young children and elderly with dementia). It is still possible

to inform these patients of the procedure and to engage their assent. **Unlike consent, assent is not determinative.** It does offer the possibility of the individual participating in their care.¹⁵

PATIENTS LACKING DECISION-MAKING CAPACITY

It is not possible to obtain informed consent when a patient lacks decision-making capacity. Necessary treatment may be provided to patients who lack decision-making capacity without obtaining the patient's informed consent. Make every effort to learn the patient's previously stated preferences for treatment (e.g., written advance directives or communication with a primary care provider). **Make efforts to obtain consent from a surrogate decision maker if prior preferences are not available.** A surrogate decision maker is a person entrusted with making health care decisions because they know the patient best and can bring the patient's values and goals into the clinical decision process. This role can be challenging for even the most capable decision makers. It is not uncommon for surrogates to have a role conflict between applying their own values and/or wishes and those of the patient.

EPs must pay attention to the language used when asking a surrogate decision maker for consent. Frame the discussion with phrases asking what the patient would want in the situation, such as "How would your father view this situation?" or "What would your father's preference be based on his values?" Avoid general phrases such as "What should we do?", "What do you want us to do?", or "What do you think he would want?" An EP can ask the surrogate "Why do you think he would choose that?" if the decision seems to stem from a role conflict. No prior conversation covers every clinical scenario perfectly, and the gravity of the decision can frequently be overwhelming for the surrogate.¹²

The choice of a surrogate decision maker may be obvious in some cases (e.g., the parent or legal guardian of a child). The choice can be more complex in other cases. Who may serve as a surrogate and their scope of authority varies by state. What if the appropriate surrogate is in question and there is no statutory guidance? A useful guide is that the surrogate's authority arises from a close relationship to the patient that affords accurate and informed communication of the patient's values. Refer challenges in resolving conflict between potential surrogates (e.g., siblings with different opinions regarding parental care) to an ethics committee or other institutional mechanisms to offer guidance unless emergent conditions make that impractical.

INFORMATION TRANSMITTAL

The EP must relate sufficient information about the procedure to the patient. This raises the questions of what information to present and how much to present. **Relevant information includes the risks and benefits of the procedure, any alternatives to the proposed course of action, and the consequences of nonaction.** The question remains how much information needs to be disclosed to patients, particularly considering the potential that legal action may be taken if an EP does not obtain informed consent properly.¹⁷

There are two standards that are commonly used, and these vary by state. The traditional "professional standard" requires the EP to provide information based on what the profession's standard of practice would deem necessary to disclose for a patient to be informed. The more common "reasonable person standard" requires the EP to include all the information that a reasonable patient would want to know to make a knowledgeable decision. Information that should be communicated includes: the patient's current medical condition and how will it progress if no treatment is given, the treatment

TABLE 1-4 Elements to Determine if a Patient Has Decision-Making Capacity

1. The patient is able to understand and process the options presented.
2. The patient is able to weight the relative benefits, burdens, and risks of the options.
3. The patient is able to apply a set of values and goals to the decision.
4. The patient is able to arrive at a decision that is consistent over time.
5. The patient is able to communicate a choice.
6. The patient demonstrates capacity appropriate and sufficient to make this decision.

alternatives, the risks and benefits of each potential treatment and their probabilities, and the financial costs of each if those estimates exist. Finally, the EP should provide a personal recommendation as to the best alternative.⁹

UNDERSTANDABLE PRESENTATION OF INFORMATION

Information must be given in a way that is understandable. The patient must be able to adequately weigh the benefits, burdens, and risks of the treatment in the context of their own beliefs, goals, life, and values. The obvious differential in knowledge and understanding between patients and EPs may be exacerbated by language barriers, literacy, low educational levels, and numeracy.¹⁸ Such barriers may be overcome by speaking at a level easy for the patient to comprehend, being sensitive to patients who may be unable to read, and being sensitive of patients who may not be highly educated. Understanding is bidirectional and necessitates that the EP confirms that the patient understands what they are told.¹⁹ Communicating numbers (e.g., risk and probabilities) is the most complex task asked of the EP.²⁰ Frame numbers in multiple ways and present outcomes in positive and negative contexts to enhance informed consent.²⁰ For example, “three out of four children have no side effects, but one in four will have nightmares from this medication.”

Language barriers are frequent in the ED and pose significant concern in obtaining and documenting informed consent.²¹ Understanding languages is situational. It is imperative to know when to call an interpreter even though some EPs may have additional non-English language proficiency. Limited language skills allow the EP to extract some critical clinical information. Patients may need more information than the EP’s skills allow. **Calling an interpreter may be essential for meeting a minimum standard of care.**²²

VOLUNTARY NATURE OF THE DECISION

Forced treatment where any real choice is removed from the patient being involved in the decision-making process violates the doctrine of informed consent. Any form of coercion based on threats or intolerable consequences (e.g., the withholding of pain medication) would fall into this category. **EPs cannot manipulate patient decisions by withholding or distorting information that the EP believes may sway the patient toward a preferred course.** Persuasion is permissible. It is an obligation as trained professionals to synthesize the information and recommend a course of action. An appropriate recommendation includes laying out the risks, benefits, and reasoning behind the recommendation as well as explaining the reasoning for not selecting an alternate approach. EPs can utilize the resources of the patient’s family or significant others to provide arguments in favor of a course of treatment. The EP must be careful to avoid overwhelming the patient, as the goal should be a shared solution by consensus and not forcing the patient to surrender to the wants of others.⁹ Strategies to approach a patient’s refusal are discussed in depth later in this chapter.

EFFECTIVE INFORMED CONSENT AND REFUSAL

There is a difference between the autonomous authorization informed consent (i.e., information and dialogue) and the effective informed consent (i.e., to meet legal and institutional requirements). **Document the discussion of the benefits, burdens, risks, and alternatives addressed in the discussion with the patient for the autonomous authorization to be recognized as effective and the entire informed consent to be valid.** Reference local institutional policies to confirm an effective informed consent or refusal.¹⁰

Some hospitals have patients sign “blanket” consent forms agreeing to all emergency tests and treatments upon their registration in the ED. Such consent forms provide no information regarding specific individual procedures.²³ These forms are not acceptable because they fail to respect patient autonomy. **Blanket consent forms cannot substitute for the usual informed consent process for procedures in the ED, where a dialogue with the patient is required.**²⁴

EXCEPTIONS TO THE INFORMED CONSENT PROCESS

EMERGENCY EXEMPTION

Society’s overriding assumption is that a person would want lifesaving treatment in an emergency. Consent to treatment is generally presumed under specific emergency circumstances where intervention is necessary to save life or limb, the harm of nontreatment is greater than the harm of the intervention, a patient is unable to participate in care decisions, and patient preferences are not known with no surrogate available. **This emergency exception is not absolute.** This is particularly true when there is clear evidence that the patient’s wishes are contrary to the intervention being considered (e.g., prehospital advance directive or a wallet card stating no blood transfusions).

Some EPs believe that any patient in the ED qualifies for an emergency exception by being in the ED. This is not true. **Location by itself cannot be used to justify the emergency exception or to infer an “implied consent” for broad ED care. The emergency exception may be invoked only when the patient will be harmed by the delay necessary to obtain informed consent.**²⁵ The EP should ask themselves a few brief questions to determine if a patient meets the criteria for an emergency exception to informed consent (Table 1-5).

THERAPEUTIC PRIVILEGE

The therapeutic privilege is a disfavored concept but recognized exception. It excuses the EP from the duty to disclose in the limited circumstances where disclosure might create harm to the patient and interrupt the treatment process. This privilege is rarely invoked as it could almost negate the entire informed consent process. Therapeutic privilege may be applied when direct disclosure to a patient would create harm, generally recognized as occurring in some psychiatric conditions and for some cultural groups.⁹

WAIVER OF INFORMED CONSENT

The EP has a duty to disclose information. Patients may differ in how they approach their participation in care decisions. Some patients may prefer that another person (e.g., a close family member) receive health care information and make treatment decisions on their behalf (i.e., delegated autonomy). This may be due to personal preference or cultural variation. The delegation of the decision-making

TABLE 1-5 Questions to Justify an Emergency Exception

1. Will failure to treat quickly result in serious harm to the patient?
2. If their condition worsens, will the patient die or suffer serious harm before definitive care can be delivered?
3. Would most capable and reasonable people want treatment for this type of injury?
4. Is the patient unable to participate in care decisions?
5. Are the patient’s preferences known or knowable in a timely way from a surrogate?
6. Is there any evidence that the patient would refuse this specific treatment?
7. Would failure to treat result in greater harm than the proposed intervention?

must be confirmed with the patient and not assumed based on cultural norms. The delegation reflects a patient's right to waive informed consent. **Honor the patient's choice to delegate that right to another person as it demonstrates an autonomous choice.**¹⁵

Some patients may interrupt the informed consent process after only partial information is disclosed and elect to follow the recommendation. If the EP confirms the patient's acceptance of the consequences of consent with only partial information, the EP may accept this as consent via waiver of the informed consent process.²⁵ The EP may accept a waiver of consent if the patient has capacity, understands that they are giving up an important right, and has made the request voluntarily. The EP who is uncomfortable with this responsibility may ask the patient to designate another person to assume this role.

IMPLIED CONSENT

Implied consent is a disfavored concept. It may be considered to "apply" in the very limited circumstances when an EP is undertaking a clinical activity with a well-known risk-benefit profile.²⁶ The most favored implied consent example is when a patient extends his arm for a blood draw. The volitional act of extending the arm is deemed as implied consent to the blood draw and its risks (e.g., pain and possible bruising). The assumption of "implied consent" poses a dangerous trap for the EP. **What an EP considers routine and well-known risks may differ greatly from what the patient knows.** This is particularly true in the ED where there is little trust and no knowledge of the patient's health literacy.

Emergency Medicine research shows at least 50% of patients wanted time spent on "detailed" information, including a review of the risks of only 1% chance of occurrence. For example, lumbar punctures are clinically safe and pose little risk. The patient perceives lumbar puncture as an invasive procedure that requires more information for informed consent.¹³ **Implied consent is not sufficient when informed consent is required or possible.**¹²

UNREPRESENTED PATIENTS OR THE PATIENT ALONE

A patient who is unable to participate in care decisions and has no surrogate decision makers is known as the "unrepresented patient" or the "patient alone." These highly vulnerable patients have no social networks to assist the care team in navigating consent and care decisions.²⁷ Attention to clinical decision-making for this patient population is growing.²⁷ Statutory guidance on decision-making for this patient population varies by region. Review institutional policies to determine whether a policy exists for decision-making for the "unrepresented patient." Consultation with the ethics service is recommended in the absence of a policy, and make efforts to develop a consistent and transparent approach to care decisions for this vulnerable population.¹⁵

INFORMED REFUSAL

The EP often begins with the presumption that patients possess decision-making capacity to consent and refuse procedures. The EP may question a patient's capacity in clinical practice more readily when the patient disagrees with recommendations.

UNDERSTAND THE REASONS FOR THE REFUSAL

A refusal for a recommended intervention should be the beginning of an important conversation with the patient. A refusal of a recommendation when first proposed may seem a rebuff or potential time challenge. Approach a refusal with openness and curiosity.

Help the patient not feel cornered into following the recommendation while confirming their informed refusal. A refusal is an opportunity to learn how to practice persuasive reasoning. A patient might have misheard numbers, or the proposed procedure may resemble a prior negative experience during the barrage of information disclosure. **Take time to listen to the patient's concerns and reasons for refusal.** This can help navigate the informed refusal process.

CONFIRM THE ADEQUACY OF INFORMATION WITH AN EMPHASIS ON UNDERSTANDABILITY

Reflect the patient's refusal reasons back to the patient so that they feel they have been heard. **It is important for the EP to acknowledge the patient's perspective, even if they disagree with the reasons.** This allows the patient to engage in listening as the EP provides additional information to support the recommendation. Normalizing an "irrational concern" allows the patient to feel "okay" and still follow the recommendation. For example, "I can understand that your sister's complication from procedural sedation several years ago would give you some concerns about this recommendation. I want to reassure you that today we take these additional steps..." Tailor the revised recommendation to address the concerns of the patient and focus on making sure that the information provided is simple, direct, and understandable.

ADDRESS BARRIERS TO UNDERSTANDING

Make significant efforts to enhance the patient's ability to understand the information when a refusal occurs. A professional interpreter must be utilized to compensate for any communication barriers to the patient's understanding in an informed refusal process. Revisit all the information from the initial discussion of information that occurred with an informal interpreter (e.g., family member or health care provider). Residual misinformation can prolong a patient's refusal. Start from the beginning of the clinical communication, even if it takes more time. This can often remedy the situation. Use language or pictures tailored to a patient's lower educational or functional level when necessary.¹⁹ Address any anxiety and pain as quickly and as safely possible as they may contribute as a barrier to understanding.

CONFIRM CAPACITY TO REFUSE RECOMMENDATIONS

Is decision-making capacity a potential issue? **The EP must take steps to mitigate any factors leading to impaired decision-making so that the patient may participate in their care to the fullest extent possible.**

It was thought in the past that patients with certain diagnoses by default lacked decision-making capacity. Many clinicians now recognize that patients with severe mental illness, early dementia, and some organic brain syndromes are at risk for impaired decision-making but may possess decision-making capacity for selected procedures and treatments.¹⁵ There are certain red-flag scenarios when an EP should scrutinize a patient's decision-making capacity with greater depth (Table 1-6). **Actions or decisions with greater consequences require a more intense evaluation of the patient's capacity.** A more careful evaluation of capacity is indicated when the patient's choice seems unreasonable or if the patient is unwilling to discuss their thought process. Chronic psychiatric and neurologic conditions remain a risk for, but should not be equated with, impaired decision-making. Cultural, educational, and language barriers impact the decision-making process. High levels of anxiety (e.g., untreated pain or the inevitable stress of the ED) are known to impair decision-making.²⁸

TABLE 1-6 Red Flag Scenarios That Require Additional Assessments of the Patient's Decision-Making Capacity

Abrupt change in mental status
Anxiety or untreated pain
Chronic psychiatric or neurologic conditions
Cultural and language barriers
Extremes of age
Limited education
Patients readily consenting to invasive or risky treatment
Refusal of recommended treatment

Many providers outside the ED setting will utilize psychiatric consultations to assist with the evaluation of a patient's decision-making capacity. The utility of such a consultation is frequently limited by time and consultant availability. Consultations in the ED may prove useful when evaluating a thought or delusional disorder that may impede understanding.

EFFECTIVE DOCUMENTATION TO DOCUMENT THE INFORMED REFUSAL

Honoring a refusal of emergency treatment that would be beneficial or may result in decompensation or death is never easy. Use of the standard hospital "Against Medical Advice" form can create an adversarial relationship that an EP may find damaging to future patient interactions and the subsequent treatment plan. Anecdotal reports include cases where patients reconsidered their decision when presented with such a document. Document refusal of care for medicolegal protection and to confirm that clear communication with the patient had occurred.

The documented recommendations when a patient refuses treatment should include: the patient has refused the recommended procedure, test, or treatment; the patient's reasons for the refusal; and the consequences of the refusal were explained to the patient including the alternatives, if any, being offered or performed in lieu of the recommended procedure. Include statements that show the patient understood and continued to refuse the specific procedure or treatment and has the capacity to do so. Document that the patient's wishes are being honored against medical advice. **It would be preferable if the EP could have the patient read this documentation followed by the patient signing the medical record below this documentation in acknowledgement.**

Additional documentation is required when an EP recognizes a "red-flag" scenario for impaired decision-making (Table 1-6) or has other reasons for concern (Table 1-7). These are essential items

TABLE 1-7 Mnemonics for Documentation of Decision-Making Capacity Assessments

U and I GLAD
U—understanding of the procedure/discussion
I—impairing conditions
G—goals and values
L—logic used to decide
A—actual functioning
D—danger or risks of decision
CURVES*
C—choose or communicate (Can the patient make and communicate their choice?)
U—understand (Can the patient understand the risks, benefits, and alternatives?)
R—reason (Can the patient make a logical and rational choice?)
V—value (Is the choice consistent with patient values?)
E—emergency (Is there impending risk?)
S—surrogate (Is a surrogate available or is there any documentation guiding treatment?)

*The first four refer to the decision-making capacity. The last two refer to treatment without consent.

that must be documented in these cases. Document the patient's medical condition and the procedure or treatment that is suggested, including the urgency and necessity. Document the patient's current decision-making abilities with a description of the impediments to capacity and the actions taken by the EP to maximize capacity. Include the availability of family or other surrogate decision makers and any relevant discussions.

Documentation will vary by institution and local laws. Being familiar with the appropriate measures to make an informed consent or refusal is effective is a critical part of the informed consent or informed refusal process in the ED.²⁹

SHARED DECISION-MAKING

There has been much discussion about the concept of shared decision-making (SDM).³⁰⁻³⁶ The concept was brought to the fore in the Institute of Medicine (IOM) report "Crossing the Quality Chasm."³⁰ It was in the context of improving quality and safety through patient-centered care, "care that is respectful of and responsive to individual patient preferences, needs, and values."³⁰ The report went on to specify "that patient values guide all clinical decisions."³⁰ There is a good deal of rhetoric surrounding patient-centered care in the literature, attempting to move clinicians away from the traditional role as the sole authoritarian and into the role of a partner in care. SDM is a way of actualizing these words, engaging patients in the essential role as a participant in their care, and breaking down communication barriers between providers and patients.

Expert consensus argues that SDM is different than informed consent.³¹ Informed consent is used when there is one distinctly superior treatment choice. The informed consent process ensures the patient understands the risks and benefits from a particular procedure and consents to the treatment freely and without persuasion. SDM is a process entered when there is more than one reasonable course of treatment indicated for a particular clinical situation, each with its own set of outcomes and potential complications. The EP and the patient exchange information involving their expertise in the process of SDM. The EP shares the potential treatment options and describes the risks and benefits of each. The patient communicates their values and preferences regarding each treatment. This is not to say that all responsibility for decisions is placed on the patient. Each person contributes to the other's understanding of important aspects of the shared decision about how to move forward with treatment. **"SDM is best described as a conversation between the clinician and the patient in which they figure out together what to do to address this patient's situation."**³¹

The mechanical approach to implementing SDM seems to disturb the spirit of a personalized strategy for a particular patient. There are some fundamental components to include in a conversation. Clarify the patient's understanding of their condition. Identify the issue requiring treatment. Offer and describe options for treatment, emphasizing the advantages and disadvantages of each. Develop an understanding for the patient's values and how they may affect preferences for treatment. What matters most to the patient? Review the understanding of the patient's preferences and move toward a decision based on a combination of available treatment data and the patient's preferences.

The ED may not lend itself well to the original approach to SDM using interventions crafted by specialists, hospitalists, and primary care providers. These tools include risk calculators, decision aids, and conversation aids. Many of these were used outside the clinical encounter. Patient deliberation regarding options is a key task supported by SDM. Implementing SDM may not always be feasible in the ED with the pressures of acuity, flow, time, and variable volume.

TABLE 1-8 The Order for Surrogates for the Delegation of Decisions

Spouse
Adult child who has the consent of other children
Majority of adult children
Parent
A person authorized by the patient
Nearest living relative
Clergy member

SDM is already occurring in the ED as we work with patients on timing of cardiac disease risk stratification, choice of imaging modalities, wound care methods, and many other procedures and pathways.

SPECIAL CIRCUMSTANCES

Consent may be obtained over the telephone if the patient is unable to consent, the surrogate is not on premises, and the surrogate is only reachable by telephone. Have two persons on the phone with the surrogate during the consent process. Note the person's name and relationship on the consent. Have both persons on the phone sign the consent as witnesses. The general order of surrogacy is noted in **Table 1-8**.

Other issues with consent arise in the ED. A person in custody retains their right to consent except in emergencies and under court orders. Contact a minor's parent or guardian for consent if they are in custody except in an emergency, under a court order, or in a situation described previously. A minor placed in adoption or in the custody of the county or state requires contact with the welfare department for consent unless in emergency. A minor serving in the U.S. Armed Forces may give consent. Pregnant minors may consent to all care related to the pregnancy and newborn.

SUMMARY

The informed consent should be performed by the EP performing the procedure. Do not have the nurse obtain the consent. A written informed consent is preferred over a verbal consent. The written consent is a record of the verbal consent. Obtain verbal consent when the patient is unable to write. Have the verbal consent signed by two witnesses to the consent. The signed consent for treatment when the patient registers is not a substitute for a consent form for the procedure. Know the institution and state requirements for consent. Involve the ethics committee if time allows.

Against Medical Advice

Ryan P. Kirby, Jessica J. Kirby, and Richard D. Robinson

INTRODUCTION

Patients electing to leave against medical advice (AMA) represent a growing population in the United States and provide unique challenges to the Emergency Physician.¹ **Discharge AMA is defined as the patient leaving before the Emergency Physician finishes the evaluation and establishes the disposition.**² It is estimated that 1% of Emergency Department visits result in a discharge AMA.^{3,4} The prevalence rate of leaving AMA varies between Emergency Departments.⁵ Discharge AMA patients often present again within a few days, resulting in increased costs associated with repeat testing and higher acuity therapeutic interventions due to worsening of their condition.³ The AMA patient has an increased risk of repeated admission, increased admission length of stay, increased morbidity, and increased mortality.^{2,6-17} This chapter provides an overview of the legal obligations to treat and elements associated with the refusal of care and discusses special populations that may be encountered.

Start with the assumption that the patient can make their own decisions, unless there is suspicion otherwise.¹⁸⁻²¹ This practice is consistent with general principles of patient autonomy. **Any decisions made must be in the best interest of the patient.** Lack of decision-making capacity requires an assessment and documentation of how this was determined (Table 2-1). Lack of capacity requires an impairment of the patient's brain or mind significant enough to interfere with decision-making. The determination of decision-making capacity is specific to a relative point in time and does not apply to later decisions. The CURVES mnemonic was developed to be used in an acute setting such as the Emergency Department (Table 2-1).

The patient has their own reasons, good or not, for leaving AMA. Not every decision by a patient is considered reasonable by the Emergency Physician.^{15,21} Patients often present voluntarily to the Emergency Department for evaluation and management. **Leaving AMA can be considered a withdrawal of the patient's consent signed when they initially presented for evaluation.**²²⁻²⁴ **The patient has the right to participate in the medical decision-making process and may refuse any care offered.**¹⁸⁻²⁰ It may be impossible to change a patient's mind once they decide to leave AMA. Sometimes it is

TABLE 2-1 The U and I GLAD and CURVES Mnemonics for Determining a Patient's Decision-Making Capacity

U and I GLAD

U—understanding of the procedure/discussion
I—impairing conditions
G—goals and values
L—logic used to decide
A—actual functioning
D—danger or risks of decision

CURVES*

Communicate: Is the patient able to choose and communicate this choice?
Understand: Does the patient understand the alternatives to treatment, benefits of treatment, and risks of leaving?
Reason: Can the patient make a rational choice?
Values: Is the patient's choice consistent with their values?
Emergency: Is there impending risk to the patient?
Surrogate: Are there patient surrogates available? Is there any documentation guiding treatment (e.g., advance directives)?

*The first four are for decision-making capacity. The last two are for treatment without consent.

TABLE 2-2 The Misconceptions Involved with Leaving AMA^{4,5,22,25,26}

AMA means the patient leaves with nothing
Blood alcohol predicts decision-making capacity
Decision-making capacity is all-or-nothing
Decision-making capacity is consistent over time
Determining decision-making capacity compromises patient safety
Forms signed by the patient offers legal protection
Insurance will not pay if leaving AMA
Leaving AMA means you can't be sued
Legal competence equates to decision-making capacity
Minors cannot give consent
Only Psychiatrists can make an accurate assessment of decision-making capacity
Psychiatric diagnoses negate a patient's decision-making capacity
The AMA form must be signed

essential to treat the patient against their wishes (e.g., altered mental status, homicidal patients, life-threatening situations, public health risk with meningitis or tuberculosis, or suicidal patients). Document these exceptions clearly in the medical record.

Many Emergency Physicians struggle internally with the AMA patient. They want to allow the patient autonomy in the decision-making process while maintaining what they believe is in the patient's best interest (i.e., beneficence). A patient going against the Emergency Physician's recommendations may set up a poor physician–patient relationship for the encounter.

MISCONCEPTIONS OF LEAVING AMA

There are many misconceptions involving the patient who is leaving AMA (Table 2-2).^{4,5,22,25,26} The main one is that a patient leaving AMA needs no further care. Offer pain medications for the patient's condition when appropriate. Do not withhold pain medications. The use of these drugs may make the patient more agreeable to completing the work-up and recommendations. This can be a new starting point and prevent the patient from leaving AMA. Offer several options for treatment if the patient refuses the primary and most ideal option. Many Emergency Physicians need to be educated regarding the misconceptions surrounding the patient leaving AMA.

RISK FACTORS FOR LEAVING AMA

Specific groups and complaints are associated with leaving AMA (Table 2-3).^{10,16,17,27-34} Many complaints are associated with extensive and prolonged work-ups. Administrators and Emergency Physicians should anticipate the needs of this group and proactively intervene to improve upon completion of the planned work-up. Early identification of these patients may prevent discharges AMA and negative outcomes. Develop strategies to prevent patients leaving AMA. Be proactive to address anger, anxiety, and emotional distress among patients.

TABLE 2-3 The Risk Factors for Leaving AMA^{10,16,17,27-34}

Abdominal pain	Lack of primary physician
Adolescents who register themselves	Lack of social support
Age 19–40 years	Lower socioeconomic status
Alcohol-related disorders	Lower triage categories
Black	Male
Chronic disease	Nonspecific chest pain
Headache	Prior AMA discharge
Hepatitis	Psychiatric disorders
Homelessness	Sickle cell anemia
Human immunodeficiency virus	Seen within last 72 hours in an Emergency Department
Lack of commercial insurance	Substance abuse
Lack of insurance	

TABLE 2-4 The Reasons Given for Adults and Children Leaving AMA^{5,6,9,14,16,17,25,31,34-41}

Anxiety about other children at home	Job issues for other family members
Change their mind	Job issues for themselves
Chronic disease	Lack of confidence in health care system
Concern for pets	Lack of confidence in physician
Conflict with child caregivers at home	Living away from home
Delays in treatment	Long waits
Disagreements with physicians	Outside obligations
Dissatisfaction with care	Poor communication with physician
Elderly parents at home	Prolonged hospital stay
Faith in local healers	Refusal of referral
Faith in religious beliefs	Refusal of surgery
Faith in social customs	Second opinion
False perception of improvement	Spontaneous resolution of illness
Finances	Spontaneous resolution of pain
Frequent blood sampling	Transportation issues
Hunger	Travel issues
Improvement with treatment	Unknown (not noted)

Improve physician–patient communication. Nurses are often first to know the patient wishes to leave AMA. Train the nurses to proactively address concerns that may prevent a patient from leaving AMA. Consider involving case managers or social workers to ensure patient needs are met and improve communication.

REASONS FOR LEAVING AMA

Patients give many reasons for leaving AMA (Table 2-4).^{5,6,9,14,16,17,25,31,34-41} The main reasons include communication issues, drug addiction, long wait times, inadequate pain control, outside obligations, physician personality, second opinions, and teaching hospital environments. Knowledge of the reasons for leaving AMA can improve the approach and management of these patients. Understanding the reasons for leaving AMA may allow Emergency Physicians and hospital administrators to address these issues and minimize adverse outcomes among this group. These patients are at risk for excessive morbidity, mortality, and increased associated costs.

Question the reason(s) the patient desires to leave AMA. Sometimes the resident or nurse can obtain this information as they typically have a closer relationship with the patient.²⁵ Consider involving family members and friends of the patient as allies to assist in convincing the patient to follow the recommendations. They may help the patient better understand the treatment and the consequences of the lack of treatment and reveal additional patient questions to be addressed. Apologize for any waits. **Do not become angry or frustrated when the patient wants to leave AMA.** This only upsets the patient and encourages them to leave even more. **Ensure the patient knows that you are on their side and have their best interest in mind.** Do not refuse to provide treatment if the patient wants to leave AMA. **Offer any treatment acceptable and appropriate for the patient's condition that they will accept.** Some care is better than no care.

DEFINING THE DUTY TO TREAT

Emergency Departments across the United States are bound by the Emergency Medical Treatment and Active Labor Act (EMTALA) requiring them to provide medical screening examinations and stabilization for all patients who present to the facility.⁴² This obligation extends to Emergency Physicians who work at facilities that participate in one or more Centers for Medicare and Medicaid Services (CMS) programs. The timeline to which the obligation extends has

been debated in the courts where allegations argue that EMTALA may even continue into the inpatient environment, as seen in the 2009 court case of *Moses v. Providence Hospital*.⁴³ One possible way the duty to treat may be terminated is via a patient's informed refusal of care.⁴⁴⁻⁴⁶ Great care must be taken in completing the process of discharging a patient AMA in terms of fulfillment of EMTALA obligations. The patient often has a high risk of readmission and increased morbidity and mortality.^{2,6-17,47,48}

ELEMENTS ASSOCIATED WITH REFUSAL OF CARE

Consent must be obtained prior to the treatment of a patient to avoid committing battery or the unwanted touching of a person (Chapter 1). Similarly, inform the patient completely before they make a final decision to refuse care.²⁶ The informed refusal of care is a process and requires more than having the patient simply sign the AMA form.

The patient may elect to refuse any or all treatment offered them during the hospital or Emergency Department encounter. **It is the responsibility of the Emergency Physician to evaluate the patient and ensure that all the elements listed below are met and then to clearly document the patient's informed decision-making process leading to refusal of care or discharge AMA.**

DECISION-MAKING CAPACITY

Decision-making capacity is sometimes simply referred to as capacity. It is determined by a physician and represents the patient's ability to make rational decisions.^{21,49} Any physician, including Emergency Physicians, who cares for a patient can clinically determine if the patient has decision-making capacity.²⁵ Consulting a Psychiatrist or their delegated representative (e.g., Psychiatric Nurse Practitioner, Psychiatric Physician Assistant, or Psychiatric Social Worker) is not necessary in most cases. It may be necessary to contact a Psychiatrist or their representative on a case-by-case basis.²² This is true when decision-making capacity cannot be determined or the patient is to be involuntarily committed (e.g., danger to others, danger to self, or incapable of self-care) to a facility. Decision-making capacity changes, is task-specific, is not all-or-nothing, and can be affected by many things (e.g., fatigue, medications, psychiatric disorders, and stress).

The term "decision-making capacity" is used by physicians. This is opposed to the legal term of competence as used by the courts.^{25,50,51} These terms are often incorrectly used interchangeably by physicians. Only a court of law can decide competency and appoint a guardian to make important decisions for the patient.

The Emergency Physician must question the patient to determine if the patient has decision-making capacity (Table 2-1). The patient must have the ability to understand information related to their condition and treatment decisions. It is not possible to assess decision-making capacity unless the patient is fully informed. **The patient must have the ability to appreciate the significance of the information presented to them. The patient must explain the information presented rather than simply repeating it back. The patient must have the ability to weigh the treatment options and demonstrate reasoning. The patient must express their choice for treatment or refusal of treatment.** Failure of one part can result in lack of decision-making capacity. All this must occur in the patient not under the influence of alcohol or drugs or not with an altered mental status. The patient must not have a reason for involuntary commitment to a facility.

The Emergency Physician must first ensure the individual patient has the capacity to participate in their own decision-making process prior to engaging in a refusal of care discussion.²⁵ **Always ensure that**

capacity exists because the decision to refuse treatment may be viewed as unreasonable. The additional use of resources from psychiatry, if available, may be of benefit. Consider other conditions that affect a patient's ability to fully participate in their care (Table 1-6). Correct any reversible causes affecting the patient's decision-making capacity. A discussion must ensue regarding the disclosure of risk following a careful review of the patient's decision-making capacity.

Formal and structured assessment tools are often used to determine decision-making capacity.^{52,53} These tools include the Aid to Capacity Evaluation (ACE), MacArthur Competence Assessment Tool (MacCAT), Montreal Cognitive Assessment (MoCA), and University of California San Diego Brief Assessment of Capacity to Consent (UBACC). These tools use standardized questions and scoring systems to objectively determine decision-making capacity. No specific test of decision-making capacity is better than another test. The tests take time to assess the patient and generate a score. Most of these tests are unfamiliar to the Emergency Physician who is untrained with their use.

Lack of decision-making capacity or refusal of treatment may allow the Emergency Physician to share information with friends and relatives. A person close to the patient can often convince the patient when the Emergency Physician is unsuccessful.²¹ This option can be explored to assess the patient's best interest. The involvement of others shows that the Emergency Physician is advocating for the patient in solicitation of additional input to make the right decision. Another physician may intervene to provide care if a patient and Emergency Physician disagree. Consider another Emergency Physician taking over the care of the patient. Consider calling the Primary Physician if the patient has one. Offer to transfer the patient to another facility. Clearly document all offers and refusals.

DISCLOSURE OF RISK

The Emergency Physician must follow the principles established in the *Canterbury v. Spence* decision when disclosing risk.⁵⁴ This requires disclosure of the condition being treated, proposed treatment being offered, alternative treatment options, and risks associated with both treatment and refusal. **Take care to ensure the patient understands all available options.** Engaging family members, friends, or on-duty Emergency Department personnel in this discussion may prove beneficial.

INSURANCE PAYMENTS

A fallacy sometimes conveyed to patients is the idea that their insurance will not pay for the visit should they elect to leave AMA.^{4,25,55} Many Residents and Attending Physicians believe insurance payments will be denied if the patient leaves AMA.⁴ They often inform the patient of this to coerce the patient in remaining.^{2,4} There are no documented instances of insurance companies denying the bill of a patient leaving AMA.⁴ There are no policies of payment denial for leaving AMA. Insurance companies determine payment based on medical necessity. The Arkansas Supreme Court in *Loretta Long v. Arkansas Blue Cross and Blue Shield* ruled that services prior to discharge are payable because of benefits due to the patient before the AMA.⁵⁶

Statements addressing the lack of insurance payment must be avoided verbally and on the AMA form.^{2,15} This appears to be an "urban legend" passed down during residency training and often persists throughout a physician's career. There is often a breakdown in the physician-patient relationship when the patient is falsely warned of negative financial consequences if leaving AMA. The insurance payment should not be a concern when caring for the patient considering leaving AMA. **The Emergency Physician must respect the patient's autonomy when they do not agree.** Resident and Attending

Physicians need to be formally educated on what to say, document, and do when the patient wants to leave AMA.

SPECIAL POPULATIONS

Obtaining a refusal of care or discharging AMA can be an anxiety-producing encounter while trying to provide care. This situation can become further complicated when a patient has consumed alcohol, is currently incarcerated, is a minor, or has an active psychiatric diagnosis. There are unique features to consider when dealing with these populations.

INTOXICATED PATIENTS

Patients who have consumed alcohol represent the most difficult of the special populations from whom to obtain informed consent or refusal.²⁹ The blood alcohol concentration can affect patients differently. The Emergency Physician often assumes that the acutely intoxicated patient lacks decision-making capacity. **The patient's decision-making capacity must first be established by the same standard as an individual who has not consumed alcohol before discharging an intoxicated patient AMA.**⁵⁷

Each individual state may have specific laws regarding the ability to give consent while intoxicated. An intoxicated patient was considered unable to provide consent and a diagnostic procedure was completed against his request in *Miller v. Rhode Island*.⁵⁸ A New York court found the hospital and Emergency Physician could not detain an intoxicated person against their will in *Kowalski v. St. Francis Hospital*.⁵⁹

Determining the degree of intoxication presents a challenge. Emergency Physicians have been previously shown to have poor ability in determining clinical sobriety. The patient often does not remember things that occurred while intoxicated when they become sober.⁵⁷ Serum and/or breath testing of alcohol does not directly correlate to a patient's degree of intoxication and is likely not helpful in determining capacity.^{60,61} Documenting the patient's activities and ability to eat, walk, engage in conversation, and to rationally understand questions and discussions can be helpful as this suggests their ability to understand care options and treatment plans. Acutely intoxicated patients may have decision-making capacity regardless of their blood alcohol concentration.^{15,57,62}

INCARCERATED PATIENTS

Patients who present in the custody of police or a correctional institution (e.g., jail or prison) represent another special population when considering the ability to refuse medical care. **Prisoners have the same rights to refuse or submit to medical care as the general population.** The standards described regarding capacity remain the same.⁶³ Unique to the incarcerated patient is their inability to determine where they are incarcerated. The correctional institution responsible for the patient may choose to supervise them in a jail ward or within a medical setting while respecting their right to refuse treatment if a patient who has capacity elects to refuse care.⁶³

MINORS

Minors (e.g., those < 18 years old) represent a special population of patients who present to the Emergency Department and may elect to refuse care. State laws vary regarding types of treatment, age of consent, and conditions that apply to a minor who presents for emergent care. A minor making one decision may not have the capacity to make other decisions. Some states allow minors to

obtain contraception, treatment for sexually transmitted infections, and treatment for substance abuse without parental permission.

Minors must be emancipated and can be determined to have decision-making capacity if they meet the following qualifications. The qualifications for emancipation vary between states. They must have the ability to understand the diagnosis, treatment or lack of treatment, and that the choices have consequences. They must have the ability to understand the information presented to them. They must have the ability to make a decision based on the information they receive from the Emergency Physician. Minors must have the ability to understand the intervention, its benefits, and its risks. They must have the ability to understand any alternatives, along with the associated risks and benefits. The minor must make a choice between treatment and lack of treatment, or choose another person to make the decision on their behalf (e.g., usually a parent or spouse). The minor cannot be coerced or forced into a decision, and pressure should never be applied.

What about the minor who lacks decision-making capacity for any reason? Decisions are often made by parents or legal guardians.⁵ Make an effort to involve the minor in order to gain their cooperation. Provide them with information in terms that they will understand based on their age.³⁵ Minors are vulnerable because they may not adequately understand the ramifications of a decision to leave AMA. Leaving AMA may not be in their best interest.

States work under the principle of *parens patriae*, or parent of the state. The state has an interest in the welfare of its citizens. This includes minors. The specifics regarding *parens patriae* vary among the states. *Parens patriae* is a mechanism for the state to override the rights of a parent and provide their substituted consent. ***Parens patriae* is not an option left to the Emergency Physician or hospital as a mechanism by which to override parental control.** Providing care in violation of parental consent may make an Emergency Physician and hospital liable for violating consent. **Do not proceed with care over parental objections without authorization from state authorities unless it is necessary to preserve life or limb.** Treatment in a true life-threatening situation can be considered prevention of child abuse, and the Emergency Physician may take emergent custody of the child. Get a second physician, if available, to agree and attest via signed documentation in a life-threatening situation to override the parents until the courts can render a decision. This may require separation of the minor from the parents with assistance from police or security.

PSYCHIATRIC PATIENTS

An active psychiatric diagnosis does not automatically mean the patient lacks decision-making capacity. An active psychiatric diagnosis may result in the lack of decision-making capacity. A psychiatric patient managed with appropriate medications can easily make decisions. Psychiatric patients may be in denial, dissatisfied with their treatment, fearful, mistrustful of the medical system, and/or paranoid. It may be necessary to contact a Psychiatrist or their delegated representative when managing psychiatric patients who refuse care.^{22,52} This is true when decision-making capacity cannot be determined or in the setting where the patient is to be involuntarily committed (e.g., danger to others, danger to self, or incapable of self-care) to a facility.

PATIENT-CENTERED APPROACH

The patient-centered approach uses shared decision-making in a collaborative effort between the Emergency Physician and patient (Table 2-5).^{2,64,65} It takes into account scientific evidence along with patient goals, preferences, and values. Shared decision-making is

TABLE 2-5 The Patient-Centered Approach for Leaving AMA⁶⁵

Determine if the patient has decision-making capability
Is the patient alert and oriented?
Does the patient have mental impairment?
Does the patient have active mental illness?
Is the patient under the influence of alcohol or drugs?
Determine the patient's preferences and values
Don't stigmatize the patient
Don't berate the patient
Don't coerce the patient
Don't express frustration
Don't express anger
Don't mention insurance will not pay if they leave
Assure the patient the decision-making has nothing to do with their ability to pay
Assure the patient the decision-making is in their interest of well-being
Involve family members personally or by phone
What is the treatment plan if staying?
Discuss the benefits and risks if staying
Discuss how treatment will differ as an outpatient
Discuss the benefits and risks if leaving
Make and provide an outpatient treatment plan if patient leaves AMA
Provide follow-up
Provide prescriptions
Provide discharge instructions
Document everything in the medical record

based on the Emergency Physician's recommendations with the patient's right to accept or refuse the recommendation. Consensus and agreement are made between the Emergency Physician and the patient when determining the goals of care that affect the patient. A more agreeable plan is made when the Emergency Physician has clear information regarding the patient's motivation and values. This involves the exchange of information, deliberation, and decision-making. Good communication with the patient is essential to avoid dissatisfaction and frustration of the Emergency Physician and the patient.

The choice to designate the patient leaving AMA is made by the Emergency Physician when they do not agree with the patient decision. A patient-centered approach is used to support informed patient choices even if they conflict with physician recommendations. Be empathetic and nonjudgmental toward the patient. Engage the patient politely to determine their motivations behind their desire to leave AMA. Explore this motivation through discussion and avoid conflict that undermines the physician-patient relationship. Embrace and respect the informed decision made by a patient who has decision-making capacity.

DOCUMENTATION

Emergency Physicians and hospitals are not unequivocally protected from lawsuits and successful litigation resulting from bad outcomes simply because the patient signs the AMA form.^{5,22,34,36,66,67} This is contrary to the belief of many physicians that the AMA form offers legal protection if the patient rejects their recommendations. Courts have found the AMA discharge terminates the physician-patient relationship and the physician's duty to treat.^{45,46} Family members often believe more could have been done for an ill patient despite the irrationality of their thinking.²² **The attending Emergency Physician, and not a resident or nurse, must interact with the patient contemplating leaving AMA and document the discussion.**

The Emergency Physician must document the situation and discussions to memorialize the encounter.⁶⁶ Clearly document the efforts offered to the patient to get them to stay. Emergency Physicians

do a poor job of documenting the encounters for patients leaving AMA.^{32,36,68,69} The documentation involves extra time and disrupts the workflow of the Emergency Physician. The Emergency Physician may be sued years after the encounter. They may only have the encounter documentation to rely upon to refresh their memory.

Many institutions elect to use standardized forms to complete the discharge AMA process (**Figure 2-1**). Many Emergency Physicians use the hospital AMA form without a clear reason. It is used to document patient symptoms, to facilitate discussions with the patient, to improve documentation, and for the ease of completion.⁷⁰ The

73 **Prototype**
EMERGENCY PHYSICIAN RECORD
Competency for AMA Discharge
or Treatment without Consent

☐ All clinical information and issues reviewed / discussed with family, patient, other _____

☐ Relevant issues reviewed / discussed with patient / family

Treating Physician _____

STATEMENT OF REFUSAL OF CARE:
(Obtain signature by patient / responsible person if possible)

I have read this paragraph. I understand that a doctor at this hospital wants to give me certain medical care. The doctor explained that care to me, and I understand what that care is. The doctor also explained to me what could happen to me if I leave here without having that care, and I understand what was said. I want to leave this hospital without receiving the recommended care.

I know that I am welcome to return to this hospital at any time to receive the recommended care or any other care that I may need at any time, regardless of my ability to pay for such care.

Patient / Person Signing on Patient's Behalf

Witness

☐ Patient / responsible person refused to sign this statement when requested to do so but indicated refusal of care in the following manner:

Other Comments: _____

FIGURE 2-1. A commercially available sample documentation for leaving AMA. (Courtesy of T-System Inc., Dallas, TX.)

form is often used to avoid further conversations with the patient. This “one size fits all” form is often just signed by the upset patient and witnessed by the staff. Signing the AMA form can appear to the patient as coercive or defensive and further exacerbate the poor physician–patient relationship.⁷⁰ The use of standardized forms has been shown to improve documentation of required elements. **Complete documentation and the patient’s signature on the AMA form are not a substitute for the informed refusal discussion.**^{34,71} The use of a hospital AMA form does not substitute for clear and specific documentation of the informed refusal documentation. Laws regarding liability are defined at the state level and vary based on jurisdiction.³⁴ Consider the AMA form as a document to make the patient aware of the benefits and risks associated with leaving AMA.³⁶ The Emergency Physician may elect to individualize and dictate the discussion with the patient (**Figure 2-2**). Document the exact words used when speaking to the patient.

Address the following elements when using a template form or directly documenting in the electronic medical record according to EMTALA guidelines: explain the clinical scenario, explain admission or treatment is medically advised, document that admission or treatment is refused by the patient, explain the potential consequences of self-discharge, and document that the patient takes responsibility for any adverse outcomes.^{34,42} Include the date of the discussion, the time of the discussion, and those persons (e.g., family, friends, and/or hospital personnel) present. The patient should have decision-making capacity and not be under the influence of alcohol or drugs. The Emergency Physician and the patient should sign if electing to use a form. An alternative is to print out the medical record and have the patient sign it. Document the lack of the patient’s signature if they refuse to sign, and have a witness to the refusal sign as well.

DISCHARGE

Provide the patient with a clear understanding of the discharge plan and alternative outpatient therapies.^{15,68,72-74} Provide any prescriptions to the patient that may be required for an alternative treatment when leaving AMA. Provide prescriptions for pain control if appropriate for the patient’s condition. Explain what to look for at home, medical reasons to return, and encourage the patient to return if they change their mind. Provide follow-up plans to the patient. Consider calling the follow-up physician to discuss the case, what was done, and why the patient left AMA to ensure appropriate care. Notify police and/or a social worker in cases of suspected child and elder abuse.

Patients electing to leave AMA can stimulate negative feelings among Emergency Physicians and staff. **Ensure that the patient feels welcome to return and resume care at any time.**^{66,74,75} This includes persistence of symptoms, worsening of symptoms, or if the patient changes their mind. **Continue to be cordial and do not give the impression that it will be held against the patient if they choose to leave AMA.** Consider calling the AMA patient in 24 hours to ensure they are better, to inquire into their safety and well-being, and to see if they have any questions. Document this discussion.

Avoid a punitive encounter to increase the likelihood that patients will obtain the care needed.^{15,74,75} The ability of the patient or their insurance carrier to pay is not an issue for the Emergency Physician to discuss with the patient. **The discharge and disclosure process must be free of coercion.** End the encounter on good terms with the patient. **Report all patients that leave AMA to risk management for review.**

The patient has decided to leave against medical advice because _____.

_____. The patient has a normal mental status, is not under the influence of alcohol or drugs, and has adequate decision-making capacity regarding medical decisions. The patient appears to have insight, judgment, and reason. The patient refuses observation or admission and wishes to be discharged. The patient presents with _____ and I am concerned for _____.

Staying for observation or admission we may be able to better treat you. The benefits and risks of leaving have been discussed and include _____,

_____ worsening illness, chronic pain, disability, and death. The benefits of observation or admission have been explained including the availability of nurses and physicians, diagnostic testing, monitoring, and treatment. The patient understands and can state the risks of leaving and benefits of observation or admission. This was witnessed by me and _____.

The patient was given the opportunity to ask questions about their medical condition, the risks of leaving, and the benefits of staying. The patient was treated with _____.

I offered to treat the patient with _____ if they stayed but the patient refused. I have spoken with Dr. _____ and the patient is to be followed up on _____ with Dr. _____.

_____. The patient was given prescriptions for _____.

_____. The patient was given discharge instructions that included they may return at any time for care.

FIGURE 2-2. A hospital-made sample documentation for leaving AMA.

SUMMARY

Emergency Physicians face ethical, legal, and medical considerations as they encounter patients presenting for care who may ultimately elect to terminate their care plans in whole or in part. An effort should be made to recognize patients at risk for leaving AMA and attempts made to educate them as to the benefits and risks of leaving AMA. Maintain good communication with the patient. Ensure that the patient has no reason to be involuntarily hospitalized. Ensure the decision-making capacity for informed decision-making and clearly document these encounters. Fully inform the patient by reviewing the risks associated with failure to complete the work-up in terms of worsening morbidity and mortality. Encouraging the patient to return at any time for further evaluation and treatment is the best practice model for navigating potential pitfalls. The Emergency Physician should always fully explain the discharge process and follow-up plan and prescribe any appropriate medications despite the patient's choice to leave AMA.

The attending Emergency Physician is responsible for the discharge AMA. Residents and nurses can help with the process. Nurses can discharge the patient in the usual manner once the attending Emergency Physician fills out the documentation. Nurses can ensure the patient has all requirements (e.g., follow-up, instructions to return, prescriptions, questions answered, etc.) upon discharge.

Family Presence

Yanina Purim-Shem-Tov and Louis Hondros

INTRODUCTION

The topic of family presence has been discussed for over 30 years, and yet it remains controversial.¹⁻⁶ The proponents of the family being present during the resuscitation argue that it is the patient's and family members' basic human right to be present during the resuscitation. They maintain that barring or excluding families from

witnessing critical events is paternalistic. Many people have already witnessed critical events in public, on television shows, on the news, on cable, and on reality shows. As a result, families are somewhat prepared and have expectations. Opponents of the family being present during resuscitation are concerned with litigation, the emotional fallout from the witnessed trauma, and disruptions during the resuscitation. The authors of this chapter strongly support the family being present during a resuscitation.

This chapter is designed to provide a reference for the Emergency Physician (EP) regarding the family being present during the resuscitation of patients in the Emergency Department (ED). It reviews the current literature on this topic and offers some suggestions.

BACKGROUND

The notion of the family being present during resuscitation dates back to the 1980s. Foote Hospital in Michigan started a program in response to families that wanted to be present during resuscitation.⁷ Data from this program were presented in 1992 as formative research and have continued to be substantiated by more current publications.⁸ The current literature shows the perspective of both the patient and the family.⁹⁻²² Most of those surveyed, including the parents of children, feel it was their right to be present during the resuscitation or invasive procedure of a family member. Furthermore, when family members are present during the resuscitation, they are more likely to believe that everything that could have been done was done for their family member.²³ In addition, 67% of parents who were present during the resuscitation of deceased children felt that being present during the resuscitation helped them cope with the death of their child.²³

Most patients with a critical illness would like to have their families present during resuscitation.^{14,21} Concern that family members will suffer from posttraumatic stress disorder (PTSD) after witnessing their loved one resuscitated has not been substantiated.^{24,25} A recent study of 65 family members of patients undergoing cardiopulmonary resuscitation (CPR) showed no difference in PTSD or depression in comparison to those who did not witness the resuscitation.¹⁶ In a multicenter randomized study, PTSD-related symptoms were significantly lower in family members who witnessed the resuscitation than the control group.¹⁷ Anxiety was also significantly lower in the intervention group that witnessed the resuscitation compared with those who did not witness the resuscitation. At 20 months of follow-up, there were no medicolegal claims of damages from the study participants.¹⁷

Professional organizations have positively endorsed the family being present during resuscitation.^{26,27} The main points from the Emergency Nurses Association (ENA) position statement are listed in **Table 3-1**.²⁶ The American Heart Association (AHA) published in its 2010 guidelines for cardiopulmonary resuscitation and emergency cardiovascular care science that, "In the absence of data documenting harm and in light of data suggesting that it may be helpful, offering select family members the opportunity to be present during a resuscitation is reasonable and desirable assuming that the patient, if an adult, has not raised a prior objection."²⁷ The AHA identified this as a Class IIa recommendation with a level of evidence "C" for adults and a Class I recommendation with a level of evidence "B" for pediatric patients. In 2015, the European Resuscitation Council recommended that family be present during a resuscitation.²⁸

Health care providers generally support the family being present during resuscitation and have identified barriers to its implementation.²⁹⁻³³ Between 86% and 96% of nurses support the family being present during resuscitation compared to 50% to 79% of physicians.²⁹ The support decreases with lower levels of training.^{5,30} The problems that health care providers perceive include

TABLE 3-1 The Emergency Nurses Association Position Statement on the Family Being Present During the Resuscitation

- There is some evidence that patients would prefer family members to be present during the resuscitation.
- There is strong evidence that family members wish to be offered the option to be present during invasive procedures and resuscitation of a family member.
- There is little to no evidence indicating that the practice of a family member being present is detrimental to the patient, the family, or the health care team.
- There is evidence that family members being present does not interfere with patient care during invasive procedures or resuscitation.
- There is evidence that health care professionals support the presence of a designated health care professional assigned to the family members present to provide explanations and offer comfort.
- There is some evidence that a policy regarding family member presence provides structure and support to health care professionals involved in this practice.
- Family member presence during invasive procedures or resuscitation should be offered as an option to the appropriate family members.
- Family member presence should be based on written institution policy developed in cooperation with the departments of social services, pastoral care, risk management, nursing, and medical staff (plus others as appropriate for the institution).
- Health care organizations should develop and disseminate educational resources to the public concerning the option of family presence during invasive procedures and resuscitation.

Source: Modified from reference 14.

anxiety, emotional stress, family litigation, limited space in the room, not enough staff to provide support to the family, prolonging a futile resuscitation, and staff distraction.³⁰⁻³⁵ The health care provider should always show respect for the patient, whether or not the family is present.³⁶ These concerns and fears have not been supported in the literature.² In a study from the Children's Medical Center of Dallas, within the study period, no interruptions occurred, none of the family members were escorted out, and no disruptive behavior occurred in 100% of cases when family members were present during the resuscitation.³³ Other studies have shown that the resuscitation or invasive procedure was not affected by the presence of family members.³⁷⁻⁴¹

HOSPITAL POLICIES

Several studies have focused on implementing hospital policies regarding the family being present during resuscitation.⁴²⁻⁴⁷ The ENA and American Association of Critical-Care Nurses (AACN) have presented specific guidelines to be included in the policies. These guidelines include the following. Describe the benefits of family presence from the perspectives of the patient, the family members, and the health care providers. Establish criteria to assess family members so that patient care is not interrupted or delayed. Identify criteria to screen family members before offering the option of being present during the resuscitation. Family members who might be excluded are those who exhibit altered mental status, combativeness, emotional distress, or intoxication. Involve the family members in the decision process regarding declaration of death, invasive procedures, or aftercare. The policy should offer the option of the family being present during the resuscitation and support family members who choose not to be present. The policy must specifically address any research approved by the hospital and conducted in the ED because patient recruitment can be difficult with the family present.⁴⁸ A health care facilitator should be designated to consult with the health care team, to obtain consensus, to ensure proper timing, and to support family members (before, during, and after the resuscitation or invasive procedure).⁴⁹ The facilitator can be a chaplain, nurse, respiratory therapist, social worker, or other

trained staff member. The option for family to be present during the resuscitation should not be offered if a facilitator is not available.^{50,51}

A survey of over 1000 nurses showed that the policies are not consistently established and that only 5% of nurses worked where policies were established.¹⁸ However, most health care providers who have experienced the family being present during the resuscitation would do it again.⁵²

PEDIATRIC CONSIDERATIONS

In July of 2014, a technical report titled "Death of a Child in the Emergency Department" was published jointly in *Pediatrics* and *Annals of Emergency Medicine*.⁵³ The report reviewed the literature and pointed out that, in the studies of pediatric trauma resuscitations, all the milestones of care were performed timely regardless of family presence.^{53,54} Most of the family members interviewed felt their presence was comforting to their children. However, a 2005 study found mixed results regarding child behavioral and emotional reflections about the family being present during the resuscitation.⁵⁵ In seven of the 17 studies, the family being present during the resuscitation resulted in a decreased level of distress. The other 10 studies demonstrated no significant difference between those who were present during the resuscitation versus those who were not. A common theme of these studies is that families believed everything was done for their loved one. In addition, numerous studies and position statements support the clinicians' ability to provide appropriate resuscitative care with the family present. O'Malley and colleagues point out this be done in the "setting of effective staff preparation, appropriate policy development and implementation, and, when staffing allows, providing designated personnel to attend to family members."⁵³

Literature from the disciplines of pediatric emergency medicine, ethics, resuscitation, and nursing overall strongly supports the family being present during resuscitation. Multiple organizations, including the ENA, American Academy of Pediatrics (AAP), and American College of Emergency Physicians (ACEP), have published position statements recommending that all EDs that care for children have a policy regarding the family being present during the resuscitation of a loved one.⁵⁴

SUMMARY

The controversy of the family being present during resuscitation has existed for some time. Review of the current literature supports family presence to be an accepted concept and practice. Most family members who have been present during a resuscitation have verbalized that they would do it again. Family members who observed the resuscitation experience reduced guilt and reduced time to accept the patient's death. They start the bereavement process earlier. The literature supports having an experienced staff member present whose only job is to support the family members during resuscitation. Data do not support the idea that family members are traumatized during resuscitation or interfere with any procedures. Medical communities should continue their efforts in establishing clear guidelines and protocols for the family being present during a resuscitation. Although most of this chapter covered family presence during resuscitation, the same principles apply to family presence during invasive procedures.

Procedures on Recently Deceased

Bryan Darger and Eric Isaacs

INTRODUCTION

An issue relevant to procedural skills in Emergency Medicine and other specialties is allowing learners to practice invasive procedures on the recently deceased.^{1,2} This often occurs immediately after the pronouncement of death and is a controversial practice. The use of the bodies of the dead for education has a long tradition in medicine. The use of the recently deceased is considered by some as a valuable resource because it improves the ability to save others in the future. Others believe consent is required from family members to preserve autonomy despite the uncomfortableness of asking for consent.

Teaching procedures have used various techniques (e.g., animals, cadavers, lectures, live patients, manikins, simulation, and videotapes). Each technique has advantages and disadvantages. These include cost, lack of reality, space, and time. The opportunity to practice lifesaving procedures is limited. This is especially true for realistic training.

Performing procedures on the recently deceased has been a topic of discussion over the past two decades and debated within the medical community. This chapter attempts to present a balanced overview of this topic and offer suggestions for best practices.

HISTORY AND CURRENT PRACTICE

Physicians and healers have been learning from the dead for millennia. The earliest-known description of circulatory anatomy is the Edwin Smith Surgical Papyrus from 1600 BC. Contemporary cadaveric dissection in the first year of undergraduate medical education training is a practice with a long precedent that has never been without controversy.

Various authorities (e.g., governments and religions) have restricted the practice of cadaver dissection for studying anatomy. A commonly cited belief is that the study or dissection of the dead without curative intent is tantamount to desecration of the corpse. There is a long intellectual and spiritual tradition of believing that the human body is sacred. This belief continues following death, and some reject dissection or manipulation as a form of desecration. This has been studied in the context of the autopsy. Some cultural or religious belief systems have requirements that the corpse of a decedent be buried whole and undisturbed. These beliefs may result in the reluctance of families to allow procedures or investigations on their loved ones after death.

An interesting footnote regarding the history of ambulance services is that they originally carried the dead to mortuaries in exchange for payment. The bodies of some patients were bought and sold to medical schools as teaching aids. Recently deceased bodies may offer the most lifelike opportunity for practicing new surgical procedures or learning anatomy.

Performing procedures on the deceased (e.g., central venous catheter placement or endotracheal intubation) is a long-standing tradition in medicine. Numerous authors have described the prevalence of this practice in the United States and abroad. This prevalence varies between specialties. More than 70% of neonatology training fellowships allowed trainees to practice endotracheal intubation and umbilical vein catheterization on recently deceased neonates.³ This practice has decreased over the past several decades, perhaps due to advances in simulation technology. A recently published survey of Emergency Medicine residencies reported that 47% of program

directors reported that this practice was ongoing at their institution, with or without official sanction.⁴

ETHICAL FRAMEWORKS AND OBJECTIONS

The general framework of medical ethics arises from four foundational principles (i.e., autonomy, justice, beneficence, and nonmaleficence). The question of whether this same framework can be readily applied to the topic of practicing procedures on deceased patients is a complex one because the “patient” is dead. The “patient” does not benefit from and is not harmed by the intervention. The “patient” does not have a formal moral standing. This may help the structured thinking about the topic.

The autonomy of a deceased person is questionable. Many do not make their preferences known before their death. The “patient” is not capable of voicing a preference or providing consent. This presents a problem for the requirement of autonomy unless these preferences were known beforehand. Collecting preferences after death is impossible outside of asking a proxy.

Beneficence and nonmaleficence are likewise difficult to consider with respect to the individual patient. The principle of beneficence may suggest that allowing a learner to practice a difficult and rare procedure on the newly deceased may allow future living patients greater chances at benefitting from an intervention and lessen the possibility of harm. A consequentialist ethical construct, a more utilitarian framework where the interests of an individual are subjugated to the interests of a larger population, might find that allowing a trainee to practice intubating someone who is dead meets the requirements of beneficence and nonmaleficence. This is due to the impact on future patients with a relative freedom from harm.

Consider the patients in whom this practice occurs to understand the principle of justice. The practice may not be equally distributed across different groups of patients or vulnerable populations (e.g., different financial classes, different sexual orientations, minorities, or those without families to speak on their behalf). It would fail this test of justice and be ethically wrong if one group were being used for procedural practice disproportionately.

PRACTICAL CONSIDERATIONS

Current practice attempts or has attempted to meet the above objections in different ways. Consent to perform procedures on the recently deceased is infrequently obtained. Policies regarding procedures on the recently deceased usually do not exist. Many lay people believe that practicing lifesaving procedures on the recently deceased is acceptable and that consent is required.^{5,6}

INFORMED CONSENT

Multiple studies have examined the practicality of obtaining consent from families to practice resuscitation skills on the recently deceased. Residents and medical students learn in their training to address bereaved relatives and to have difficult conversations. The use of a loved one for procedural practice after they are deceased is a request that is intuitively uncomfortable. However, many families have given informed consent to use recently deceased babies for intubation if it helped to save other babies in the future.³

The reliance on familial consent sometimes does not follow the patient’s wishes.⁴ Presumed consent is problematic since the patient does not receive the benefit of the procedure. Health care personnel and medical trainees are often apprehensive and uncomfortable when procedures are performed on the recently deceased without consent. Obtaining consent respects the family, health care personnel, and medical trainees.

In Ohio, a person can be charged for practicing procedures on the recently deceased. The charge is abusing a corpse. This is based on the revised Code ORC 2927.01. The Code states the following: “(A) No person, except as authorized by law, shall treat a human corpse in a way that he knows would outrage reasonable family sensibilities. (B) No person, except as authorized by law, shall treat a corpse in a way that would outrage reasonable community sensibilities. (C) Whoever violates Division (A) of this section is guilty of abuse of a corpse, a misdemeanor of the second degree. Whoever violates Division (B) of this section is guilty of gross abuse of a corpse, a felony of the fourth degree.”

SLOW CODES

An alternative form of teaching or allowing trainees to learn procedural skills is the continuance of resuscitative efforts with the purpose of allowing the practice of procedures (e.g., arterial line insertion, central venous line insertion, or pericardiocentesis), not because the resuscitation leader thinks it will lead to a successful resuscitation. This has been termed running a “slow code” by some. The American Nurses Association has issued a statement on so-called slow codes or submaximal resuscitation efforts.⁷ They note that slow codes are not ethical and that partial codes often are not appropriate because they offer even less potential for survival than full codes.⁷ With only a few exceptions, partial attempts to reverse a cardiac or pulmonary arrest are medically unsound because these interventions are often highly traumatic and consistently ineffective.⁸ A slow code often violates the principle of nonmaleficence.

Some might question why this practice is not morally defensible when compared to practicing procedures on the recently deceased. Consider the potential harms, including cardiopulmonary resuscitation-induced consciousness and suffering, return of spontaneous circulation with poor neurologic outcome, and familial and medical professional distress. It quickly becomes clear why performing a slow code is ethically problematic.⁹

ADDITIONAL CONSIDERATIONS

Consider the relative invasiveness and lasting consequences on the body of various procedures when thinking about procedural practice in the deceased. Are some procedures that do not leave a mark on the outside of the body (e.g., endotracheal intubation attempt) or leave the body “intact” more acceptable to perform? Are more invasive procedures (e.g., surgical airways or a thoracotomy) that leave an external mark less acceptable? One study has suggested that family members are more comfortable with less invasive procedures than they are with more invasive procedures.¹⁰

Consider available alternatives for training. Clinicians practicing in an austere environment in developing countries have few alternatives for learning, so training on the recently deceased might be considered more permissible than if one practices in an environment with adequate hands-on opportunities with appropriate oversight and backup in living patients who can provide consent for a procedure, with ready access to preserved cadavers who gave antecedent consent to being used for learning, or with simulation facilities. Many manikins and animal models have been developed to address these issues but lack realism.

The legislature of individual states and the US Congress could develop a preauthorization form similar to organ donation. This form would have numerous advantages. The use of slow codes would be eliminated to teach procedures. Health care personnel would feel more comfortable. Hospitals would not have to make policies, and the administrators would not need to be involved. The need for family consent is avoided if the patient’s wishes are known.

The form would avoid using certain groups of patients more often than others.

NATIONAL GUIDELINES FROM THE AMERICAN MEDICAL ASSOCIATION

A series of articles and editorials in the lay press and the medical literature brought attention to the issue of performing procedures on the recently deceased. The Council on Ethical and Judicial Affairs of the American Medical Association (AMA) published a report on the topic in 2002.¹¹ A panel of experts was convened and published a document that focused on the question of the necessity of consent and offered the below recommendations regarding practice of procedures on the newly deceased.

Work to develop institutional policies that address the practice of performing procedures on the newly deceased for purposes of training. Include in any policies that the interests of all the parties involved are respected under established and clear ethical guidelines. Consider the rights of patients and their families, benefits to trainees and society, the potential harm to the ethical sensitivities of trainees, the risks to staff, the risks to the institution, and the risks to the profession associated with performing procedures on the newly deceased without consent. The lack of consent can damage the reputation of doctors and hospitals.

Address the following before trainees perform procedures on the newly deceased. The teaching of lifesaving skills should be the culmination of a structured training sequence, rather than relying on random opportunities. Training should be performed under close supervision. The environment and manner of performing procedures on the recently deceased should account for the wishes and values of all involved parties. Inquire whether the deceased individual had expressed preferences regarding handling their body or procedures performed after death. Request permission from the family in the absence of previously expressed preferences before performing procedures. Do not perform procedures for training purposes on the newly deceased patient when reasonable efforts to discover previously expressed preferences or someone with authority to grant permission for the procedure have failed.⁹

GUIDELINES FROM EMERGENCY MEDICINE PROFESSIONAL ORGANIZATIONS

The American College of Emergency Physicians (ACEP) Ethics Committee developed an information paper on the issues surrounding the practice of performing procedures on the newly dead but stopped short of developing an explicit statement on whether consent is required.¹² They recommended further research on the ethical ramifications, feasibility, public opinion, and consequences of asking for familial consent. Work has continued in these areas, although perhaps not at the pace requested.

An article published in 2004 offered a position from the Society for Academic Emergency Medicine.¹³ It offered arguments both for and against this practice. It concluded by encouraging all Emergency Medicine training programs to develop a policy and make that policy available to the educators, institution, public, and trainees. It also recommended that families be asked for consent prior to practicing any procedures on the deceased.

SUMMARY

Procedural skills and proficiency are an incredibly important part of training in Emergency Medicine and many other medical specialties. Teaching these skills on living patients is the gold standard but has numerous potential downsides (e.g., the potential for unintended harm to patients as skills are attained). We are making rapid

TABLE 4-1 Some Recommendations for Using the Newly Deceased for Procedures**Conditions to be met:**

- Consent is obtained before the procedure from a legal representative of the patient
- Documentation in the medical record of all other persons present
- Documentation in the medical record of any complications from the procedures
- Documentation in the medical record of consent and from whom
- Documentation in the medical record of the person performing the procedure
- Documentation in the medical record of a procedure note for any procedure performed
- Documentation in the medical record of the procedures performed
- Procedure performance is appropriate for the trainee
- Procedure performance is appropriate for the training program
- Procedure performance is supervised by faculty presence
- The cost will not be billed to the patient, the family, or the insurance company

Do not perform procedures if:

- Advance directives are against the procedures being practiced
- Consent is not obtainable due to lack of any legal representative
- Consent is not obtainable due to refusal of consent
- It is a medical examiner's case
- Member(s) of the health care team does not believe the procedure is appropriate
- The patient is a child unless the parents' consent
- Procedures are against cultural or religious beliefs
- Procedures interfere with an autopsy
- Procedures interfere with forensic evidence collection
- Procedures interfere with family visitation
- There is suspicion of patient abuse
- There is suspicion of patient neglect

progress as a profession in the use of simulation in training but have a long way to go before it can be used to its full potential. The practice of allowing trainees to perform invasive and noninvasive procedures on the recently deceased offers one way of gaining experience and technical skill without the possibility of patient harm.⁹ The final recommendations are listed in **Table 4-1**.

Any personal or institutional approach to this practice must account for the ethical and pragmatic considerations. Balance the needs and interests of society and future patients with the legitimate interests of patients and their families. For the time being, it is likely that this practice of performing procedures on the newly deceased will continue. It should be done with care and thought. The consent of patients and their families will occur in ideal circumstances. Academic institutions and hospitals should talk about these issues before they arise and develop transparent policies that reflect a commitment to patient care above all else.

In the future, medical education and simulation will continue to progress. The use of simulation training mannequins and virtual reality technologies will become more prevalent, and the need for discussing this issue may be eliminated.

5**Aseptic Technique**

John S. Rose

INTRODUCTION

The proper use and understanding of aseptic technique are critical for the care of patients in the Emergency Department (ED). Aseptic technique dovetails with prescribed universal precautions and is central to the practice of Emergency Medicine. Knowledge of proper aseptic technique ensures that procedures performed in the ED provide maximal protection for the patient and the Emergency Physician while keeping the risk of contamination as low as possible.¹⁻¹⁹

Wound infection and sepsis are the two major complications resulting from poor and improper aseptic technique. Other complications that may contribute to the patient's morbidity and mortality include increased length and cost of hospital stay, patient discomfort, scarring, and death. **Aseptic technique is warranted except in the direst circumstances.**

Numerous terms are used to describe the establishment and maintenance of a "sterile" environment. These include aseptic, disinfection, and sterile technique, to name a few. Many people often incorrectly interchange these terms. The proper definitions of the terms used to describe aseptic technique or associated with it can be found in **Table 5-1**.

ANATOMY AND PATHOPHYSIOLOGY

The skin and hair are colonized with various organisms. The stratum corneum layer of the epidermis is colonized with a polymicrobial flora. This includes molds, *Staphylococcus aureus*, *Staphylococcus epidermidis*, various *Streptococcus* species, viruses, and yeasts. Many of these organisms are nonpathogenic, even when placed in environments considered appropriate for infection. ***S. aureus* is the most common cause of wound infections.** It can result in an infection when introduced into deeper skin layers. Some species (e.g., *S. epidermidis*) are pathologic only when inoculated into deeper layers of the skin and soft tissue. A significant inoculation is required for most infections to create a critical level for microbial growth. **Aseptic technique decreases bacterial exposure and reduces the level of potentially pathologic organisms.**

TABLE 5-1 Definitions of Terms Used to Describe Aseptic Technique or Associated Processes

Term	Definition
Aseptic	Freedom from infection. Prevention of contact with microorganisms. Involves the use of sterile technique and skin disinfection.
Clean technique	The practice of using nonsterile equipment to perform procedures. This is considered as part of the universal body fluid precautions.
Disinfection	The cleaning of an area to make it free of pathogenic organisms and microbes.
Sterile field	The zone in which strict sterile technique is maintained. Generally consists of an area 3 to 10 times larger than the area of the primary procedure.
Sterile technique	The practice of utilizing sterile equipment and procedures to maintain an aseptic environment.
Super aseptic	Ultra-high state of an aseptic environment. Usually, this is achievable only in the operating room.

INDICATIONS

The role of aseptic technique in the ED is primarily for invasive procedures. Invasive procedures require varying degrees of aseptic technique. Placement of a small peripheral intravenous catheter may require no more than a brief wiping of the skin. A diagnostic peritoneal lavage requires Operating Room-level disinfection and strict sterile technique.

Routine and adequate provider disinfection involves careful hand washing, the use of clean and disinfected personal diagnostic equipment (e.g., stethoscopes), and wearing appropriately cleaned coats and clothing. This is critical in preventing iatrogenic infections in the ED. Aseptic technique in the ED can be referred to as clinical aseptic technique, since it is virtually impossible to achieve an Operating Room level of asepsis. **Clinical aseptic technique involves the combining of adequate disinfection with sterile techniques and protocols at the bedside.**

CONTRAINDICATIONS

There are very few contraindications to the maintenance of adequate clinical aseptic technique. One exception would be that extreme clinical circumstance in which time simply does not allow proper aseptic technique (e.g., an emergent thoracotomy). The Emergency Physician can still use sterile gloves and a quick application of an aseptic solution.

Always inquire about allergies and sensitivities to latex and anti-septic solutions. This information will affect the equipment that is chosen to properly prepare the patient.⁸ Hospitals have a latex-free cart that contains equipment for use with latex-allergic patients. **Do not use povidone iodine solution in patients allergic to iodine.** Alternative agents include chlorhexidine and hexachlorophene preparations.

There are some relative contraindications to using some disinfectants. Do not use alcohol-based disinfectants near the eyes, inner ear, mucous membranes, or open wounds. Chlorhexidine can damage the corneal epithelium. Use only ophthalmic-approved iodine-based disinfectants. Chlorhexidine can cause deafness if it reaches the inner ear. Use aqueous-based disinfectants for the ears. Use chlorhexidine with caution around the mucous membranes. Check manufacturers' recommendations or use an aqueous iodine-based disinfectant.

EQUIPMENT

- Povidone iodine solution
- Chlorhexidine gluconate (i.e., chlorhexidine) or hexachlorophene-based solutions
- 70% isopropyl alcohol
- Sterile 4 × 4 gauze squares or applicator sticks
- Sterile gloves
- Face mask and eye protection
- Sterile drapes or towels
- Adequate lighting
- Sterile gowns
- Surgical hat
- Bedside procedure table

PATIENT PREPARATION

Inform the patient of what the procedure entails before performing any procedure in the ED. This should include an explanation of sterile technique and a request that the patient not touch the drapes or sterile equipment. Obtain any required informed consent (Chapter 1) before the patient is draped. The only exception to this is if an emergent and lifesaving procedure must be immediately performed.

Place the patient in the most comfortable position possible. Patient discomfort frequently results in movement and the potential loss of the sterile field. Use sedation and/or analgesia (Chapters 153 to 159) as necessary to facilitate proper patient positioning. The Emergency Physician must also be comfortably positioned if possible and have adequate lighting.

TECHNIQUES

Aseptic technique can be divided into skin disinfection and sterile technique. Skin disinfection removes any microorganisms found on the skin and decreases the potential contamination during the procedure. Sterile technique is performed for the same reason. There are different levels of aseptic technique, ranging from full aseptic technique (i.e., cap, mask, sterile drapes, sterile gloves, and sterile gown) to simple sterile gloves. The physician must use their judgment to determine which level is most appropriate to the task at hand.⁸

SKIN DISINFECTION

Disinfection involves the application and scrubbing of a disinfectant preparation onto the skin. Simple procedures (e.g., injections or venipunctures) may require little disinfection. Wipe the skin with gauze that has been impregnated with 70% isopropyl alcohol for simple procedures. The alcohol has an antibacterial effect. **The mere force of wiping the skin reduces bacterial counts.** No disinfection is used for simple venipunctures in some countries. More comprehensive skin preparation involves the use of a disinfectant agent (e.g., chlorhexidine solution or povidone iodine).

Chlorhexidine, povidone iodine, and 2% iodine tincture are the most commonly used skin antiseptic solutions. Povidone iodine solution is highly germicidal for gram-positive and gram-negative bacteria, viruses, fungi, protozoa, and yeasts.⁷ It rapidly reduces bacterial counts on the skin surface and can last up to 3 hours.^{7,11} Allow the iodine solution to dry and then wipe it from the skin with 70% alcohol prior to beginning the procedure. **The iodine solutions work by oxidation and cross-linking of sulfhydryl groups, killing bacteria as the solution dries.** Isopropyl alcohol can be applied

to the skin and scrubbed vigorously for 2 minutes to achieve disinfection, although this may cause skin irritation. Chlorhexidine or hexachlorophene preparations may be routinely used or used as substitutes in iodine-allergic or sensitive patients. These agents provide good bactericidal activity against gram-positive bacteria but somewhat less activity against gram-negative organisms.⁸

Chlorhexidine-based solutions are being used more commonly and are replacing the iodine-based solutions. Chlorhexidine provides much longer antimicrobial activity (e.g., up to 48 hours) and is gentler on the skin than iodine.¹¹⁻¹⁵ **Chlorhexidine destroys cell membranes of gram-positive and gram-negative bacteria while precipitating the intracellular contents.** Some preparations contain 70% isopropyl alcohol, further enhancing the antimicrobial activity.¹²⁻¹⁴ The use of chlorhexidine solutions is superior to iodine solutions.^{14,15,17,19}

Use a skin disinfectant for procedures other than simple venipuncture. Place the disinfectant solution onto a sterile sponge or sterile gauze if it is not supplied inside a single-use applicator. Historically, the application of disinfectant to the skin has been in a circular motion, beginning with the central area of the procedure and working out toward the periphery of the sterile field (**Figure 5-1**). There is no evidence to support this application method. It has been suggested that scrubbing in a back-and-forth motion may be preferable because it creates friction to dislodge microbes.^{9,10} The back-and-forth motion drives the disinfectant solution into skin crevices and deeper layers, thus killing more bacteria and hopefully preventing infections.

Regardless of the disinfectant solution used, repeat the application process three or four times using a new sponge, gauze square, or applicator each time.⁸ The technique of applying the disinfectant several times ensures that the central area where the procedure is to be performed is the most sterile area of the field. **The area of disinfection must be much larger than the primary area of the procedure, as the number of organisms increases toward the periphery of the prepped area.**

STERILE TECHNIQUE

General sterile technique is described followed by specific details for each step of the procedure. Strict sterile technique is virtually impossible in the ED. **Make every effort to maintain a sterile field to minimize infection.** Assemble all equipment necessary and place it on a small procedure stand. **Do not use the patient or their bed to set up supplies or equipment.** Patient movement and their irregular body surfaces can result in items becoming contaminated, breaking, or falling or iatrogenic needle sticks. Avoid having different components scattered around the procedure area. Open all sterile items, using proper sterile protocol, to have them available once the Emergency Physician has donned sterile gloves. Use anesthetic solution containers with removable caps. This allows the Emergency Physician to draw up anesthetic without having an assistant and minimizes the risk of occupational needle exposure. **Perform a thorough hand washing before the procedure.**

Use eye, face, and hair protection during the procedure. Apply these before donning sterile gloves and sterile gowns. Apply sterile gloves. Place sterile drapes or towels on the patient to form a field wide enough to allow for a comfortable work space. Drape the area near the patient closest to the bedside procedure table. This will minimize inadvertent contamination in moving from the table to the patient. Make a small flat sterile area near the procedure site to allow for placement of important items that must be immediately available. **Open all caps, position stopcocks, and prepare all devices prior to starting the procedure.** The likelihood of contamination increases if devices are not adequately prepared and require manipulation during the critical portion of a procedure. **Adhere to universal precautions guidelines.**

FIGURE 5-1. Preparation of the skin. Disinfectant solution is applied in a concentric circular pattern starting from the procedure site and working outward. Apply the disinfectant solution with sterile gauze held in a clamp (**A**), with sterile gauze held in a sterile gloved hand (**B**), or with a sponge on a stick (**C**).

OPENING A STERILE PACK

Always make sure that the outer wrapping is intact, the sterility expiration date has not passed, and the sterility indicator tape is the appropriate color before opening a sterile pack.² Wash your hands and then remove the outer wrap if applicable. Remove the sterility

indicator tape (**Figure 5-2A**). Place the sterile pack on a dry and level surface with the outermost flap facing away from you (**Figure 5-2B**). Grasp the corners of the outermost flap (**Figure 5-2B**). Hold your arms to the sides of the pack to avoid reaching over the sterile area. Lift the flap up and away (**Figure 5-2B**). Open the side flaps by grasping the folded corner with a thumb and index finger and pulling the

**A****B****C****D****E**

FIGURE 5-2. Opening a sterile pack. **A.** Remove the sterility indicator tape. **B.** Grasp the edges of the outermost flap and open it away from you. **C.** Open the side flaps. **D.** Open the remaining flap toward you. **E.** The open pack.

flap to the side (**Figure 5-2C**). Open the bottom flap (**Figure 5-2D**). Grasp and open the bottom flap while stepping back to prevent contaminating the wrap on your clothing. **Make sure that your arms and clothes do not contaminate the contents of the pack when opening the flaps.** Repeat the procedure if the pack has an inner wrap.

PLACING STERILE SUPPLIES ON A STERILE FIELD

Sterile supplies are generally packaged in a hard peel-back pack (i.e., hard pack) or a soft peel-back pack (i.e., soft pack). The general principle of opening these is the same, although there are subtle differences. Hold the hard peel-back container in the nondominant hand with the flap facing the sterile field (**Figure 5-3A**). Pull the flap toward you with the dominant hand so that the open end of the pack will be facing the field (**Figure 5-3A**). Hold the container 15 to 20 cm above the sterile field. This ensures that if the contents fall, it will be onto the sterile field where they are wanted. Drop the contents of the sterile pack onto the sterile field taking care not to contaminate the field with the container (**Figure 5-3B**).

Gloves and syringes are wrapped in soft packs. Grasp both sides of the unsealed edge of the soft pack and pull them apart slightly

A

B

FIGURE 5-3. Opening a hard peel-back container. **A.** Grasp the container with the flap facing the sterile field. Remove the flap. **B.** Drop the contents of the hard container onto the sterile field.

FIGURE 5-4. Opening a soft peel-back container. **A.** Grasp both sides of the unsealed edge and pull them apart. **B.** Face the pack toward the sterile field. Continue to open the edges until the contents fall onto the sterile field.

(**Figure 5-4A**). Hold the open end facing the sterile field (i.e., away from you). Continue to open the soft pack. Fold the sides of the sterile packing back and over your hands to keep the contents sterile (**Figure 5-4B**). Gently drop the contents of the soft pack onto the sterile field.

APPLICATION OF A MASK

Surgical masks serve a dual role in the performance of aseptic technique. Masks have been shown to decrease contamination of the sterile field that may result from aerosolized droplets from the mouth and nose. Masks protect the caregiver's mucous membranes from exposure and possible splashing during the procedure. Wear a mask with an eye shield during high-risk procedures.

Apply the mask before donning gloves and other sterile equipment. Secure the mask by placing the elastic straps around the ears, placing the elastic straps around the head, or tying the mask securely to the face with ties around the head and neck depending on the type and style of the mask. Pinch the metal nose clip securely to the bridge of the nose for a tighter fit and to minimize the gap between the mask and the nose.

HAND WASHING

An Emergency Physician must thoroughly wash their hands despite wearing sterile gloves for all sterile procedures. Do not overlook good hand washing technique. A full surgical scrub is neither necessary nor feasible in the ED.

Rinse your hands in warm water prior to applying antiseptic soap. Apply soap, lather your hands, and rub them together vigorously for approximately 10 seconds. Wash each wrist with the opposite hand. Interlace the fingers of both hands and slide them back and forth to clean the web spaces. Clean around the nails with the fingertips and nails of the opposite hand. Completely rinse each hand from the fingers downward. Repeat the procedure a second time if your hands were grossly contaminated. Dry your hands with a disposable towel. Turn off the faucet, using the towel with which you dried your hands. **Do not touch the faucet with clean hands to prevent them from being recontaminated.**

APPLICATION OF A CLEAN GOWN

A clean (i.e., nonsterile) gown is often used as an additional barrier to prevent contamination of the field and the Emergency Physician's

clothing. Simply place your arms into the sleeves and pull on the gown with the opening toward the back. Secure the gown at the back of the neck and the lower back by tying the strings.

APPLICATION OF A STERILE GOWN

A sterile gown is worn for procedures requiring a stricter sterile technique (i.e., central venous access or diagnostic peritoneal lavage). Use the procedure previously described to open a gown's sterile soft pack. Grasp and pick up the gown just below the neckline, touching only the inner surface of the gown. Hold the gown up and let it unfold with the inside facing you. **Do not allow the gown to touch any nonsterile surfaces.** Insert your arms into the sleeves until the gown is in place. Have an assistant grasp the back of the gown, pull it completely on, and tie the strings securely.

APPLICATION OF STERILE GLOVES

Wash your hands thoroughly before putting on sterile gloves. Apply a clean gown at this point if it will be worn during the procedure. Open the outer wrap of the sterile gloves and remove the inner wrap. Open the outer wrap of the sterile gloves and remove the inner wrap (Figure 5-5A). Place the inner wrap on a clean

surface with the gloves' wrists facing toward you. Unfold the inner wrap touching only the outside edges (**Figure 5-5B**). Open the inner wrap according to the procedure for opening a sterile pack (**Figure 5-5C**). Apply a sterile gown if it will be worn during the procedure. Use the dominant hand to grab the opposite glove at the inner edge of its folded cuff (**Figure 5-5D**). Slip the nondominant hand into the glove (**Figure 5-5E**). **Be careful not to touch the outer surface of the glove (Figure 5-5E).** Pull the glove further onto the nondominant hand using the inner edge of the cuff (**Figure 5-5F**). Place the fingers of the gloved nondominant hand into the folded cuff of the other glove (**Figure 5-5G**). Slip the dominant hand into the glove (**Figure 5-5H**). Pull this glove over the dominant hand using the cuff (**Figure 5-5I**). Carefully unfold the cuff of each glove. **Use care not to touch the fingers and palms of the gloves to nonsterile skin.** Adjust each glove to ensure a snug fit over the fingers and hand.

REMOVAL OF PROTECTIVE CLOTHING

Remove protective clothing in a systematic manner to protect yourself and others from the contaminants on the gown and gloves (**Figure 5-6**).²⁰ Place all removed garments into the appropriate waste containers. The first step is to untie the gown (**Figure 5-6A**). Have an assistant untie the neck strings of the gown or pull on both shoulders of the gown to break the neck strings. Untie the waist strings. Take off the gown by turning it inside out as it is removed (**Figure 5-6B**). Roll up the gown with the contaminated surface facing inward and away from you (**Figure 5-6C**). Dispose of the gown. Remove the gloves by turning them inside out. **Make sure that you do not touch the outside contaminated surface with ungloved hands.**²⁰ Use the dominant hand to grasp the cuff of the glove on the nondominant hand (**Figure 5-6D**). Pull the glove inside out as it is removed and throw it away. Place the ungloved

FIGURE 5-6. Removal of protective clothing. **A.** Untie the gown. **B.** Remove the gown by turning it inside out. **C.** Roll up the gown with the contaminated side facing inward. **D.** Remove the glove from the nondominant hand. **E.** Remove the glove from the dominant hand. Remove the face mask and wash your hands.

fingers of the nondominant hand into the inside edge of the gloved dominant hand and remove the glove by pulling the glove inside out (**Figure 5-6E**). Dispose of the glove. Remove the mask by untying its ties or removing the elastic straps from behind your ears. Dispose of the mask and wash your hands.

ULTRASOUND TRANSDUCER PREPARATION

Ultrasound is commonly used for many procedures. The application of sterile transducer covers allows for real-time and dynamic sonographic assessment during a procedure. Prepackaged transducer covers are available and are often included in procedure kits.

Open the prepackaged sterile transducer cover kit. Identify the sterile coupling gel, cover, and associated rubber bands to securely cover the transducer (**Figure 5-7A**). Apply coupling gel to the transducer (**Figure 5-7B**). Insert a gloved hand onto the front portion

of the cover and push it inside out (**Figure 5-7C**). Carefully grasp and hold the transducer through the cover (**Figure 5-7D**). Apply the remaining cover over the transducer (**Figure 5-7D**). Expel all the bubbles from the gel at the face of the transducer. Apply the supplied rubber bands to secure the cover in place (**Figure 5-7E**).

DOUBLE GLOVING

Some Emergency Physicians wear two gloves in case the first one is cut. This offers some protection against the patient's blood and body fluids. The second glove sometimes protects against bloodborne pathogens. It may be hard to tell when the glove is cut if the skin is cut or intact until the glove is removed. Companies are now making double-dipped, dual-color gloves (**Figure 5-8**). These gloves are twice as thick as ordinary gloves. Cutting the outer white surface exposes the underneath color, making it easier to see glove perforations.

Rubber bands are applied to secure the sterile cover.

FIGURE 5-8. An example of a double-dipped dual-color glove.

COMPLICATIONS

Properly performed aseptic technique has very few complications. The primary risk is in patients with sensitivities or allergies to latex or the disinfectant preparations. Povidone iodine preparations are much less irritating than tincture of iodine. It is a good policy to clean all disinfectant off the patient at the end of the procedure to minimize any skin irritation. This is especially true of small children. Use alternate products for those patients with histories of allergies. **The main complication of improper aseptic technique is infection at the site of the procedure.⁸ This only serves to underscore the need to perform aseptic technique properly.**

SUMMARY

Aseptic technique is an important component of all invasive procedures performed in the ED. Adequate skin disinfection and the proper use of sterile technique will greatly decrease the risk of iatrogenic infections. Aseptic technique allows a degree of protection for the Emergency Physician and the patient. Choose the level of asepsis required for the individual procedure.

Basic Principles of Ultrasonography

Basem F. Khishfe

INTRODUCTION

The Emergency Physician (EP) has performed bedside ultrasound (US) for more than three decades. US is ubiquitous today in Emergency Medicine (EM). Each year, new EPs learn the skill, fresh evidence is brought to light supporting the practice, and novel indications are explored.¹ Technological advances have delivered smaller machines with improved image quality that are less expensive than ever before. US training is an important component of an EM residency program and a required core competency procedure of the Accreditation Council for Graduate Medical Education Residency Review Committee.² It is tested on board examinations and is endorsed by EM societies.^{1,3} There are numerous opportunities for supplementary training in emergency US ranging from local courses to established fellowship training programs.

Safety considerations have also contributed to the acceptance of bedside US. Sonography is noninvasive, is safe in pregnancy, does not involve ionizing radiation, does not require nephrotoxic contrast agents, does not cause subcutaneous extravasation, and does not cause allergic reactions like other modes of imaging.⁴ With increasing concern in the medical community over the long-term effects of ionizing radiation, US is recognized as an attractive alternative.⁵ The U.S. Department of Health and Human Services Agency for Healthcare Research and Quality has highlighted US guidance for central line insertion as one of their top 10 recommended practices.⁶

The intent of this chapter is to provide an introduction to bedside US. The physician-sonographer should have a general understanding of the physics underlying the properties of an US wave.

“Knobology” is a colloquial term used to describe the study of the buttons, dials, switches, and knobs on the console of an US machine. **It is important that all users have a good sense of their machine’s operational functions.** Typical US machines and transducers used in the ED will be described.

BRIEF HISTORY OF EMERGENCY ULTRASOUND

Bats and toothed whales have used sound for echolocation for millions of years. Dolphins produce a series of clicks that pass through the lipid-rich melon on their heads, an acoustical lens of sorts that focuses the sound waves into a beam. Returning echoes are processed to determine the location of objects for navigation and hunting.⁷ Sonar (acronym for *sound navigation and ranging*) is a maritime technique that uses sound waves for identifying oceanic objects. It was initially introduced in response to the sinking of the *Titanic* in 1912.⁸ It was further developed and employed in World Wars I and II for submarine detection.⁸

In the early 1950s, a Radiologist named Douglas Howry and a team of other physicians introduced the first diagnostic US machine using a water-bath immersion tank. In the 1960s, direct contact (i.e., transducer to patient) scanners were developed, and the contemporary saga of US as a viable diagnostic modality commenced.⁹ The technology was only found in specialized imaging laboratories. US technology improved rapidly. Real-time US was developed in the 1980s, allowing the viewing of images without delay between signal generation and the display monitor. US devices continued to improve, and technological advances have delivered smaller portable machines with improved image quality that are less expensive than ever before. The clinical applications growth paralleled those advancements. As early as the 1970s, Surgeons in Germany experimented with US to detect free fluid in the abdomen.¹⁰ In the late 1980s, EPs began investigating the clinical use of US. The American College of Emergency Physicians (ACEP) offered its first course in emergency applications of US in 1990.

US has been examined over the past two decades and used for a wide spectrum of clinical conditions. A number of factors helped the development of emergency US, including the growing recognition of the utility of US information, the improved US technology, the accessibility to bedside US machines, the need for timely access to diagnostic imaging, and the endorsement of US by the EM societies. Several US manufacturers have developed machines targeted to EM, taking into consideration the specific indications and the less-than-forgiving work environment.

In the early years of emergency US, EPs often used large tank-like machines that were not conducive to a fast-paced work environment. Small portable machines that produce high-quality images are now available. Many US devices are the size of laptop computers that fit on maneuverable carts. Pocket-sized machines, not much larger than mobile phones, are being introduced and offer even greater portability. The notion of the “sono-stethoscope” promises devices as small, easy to use, and available as the stethoscope, but with the superior insight of sonography.

THE PARADIGM OF BEDSIDE ULTRASOUND

Bedside US offers a relatively new paradigm in clinical medicine. Traditional US involves a break in the patient–physician encounter. The multistep process involves the EP evaluating the patient and determining that an US is warranted, the Radiologic Technologist performing the study in an US suite, the Radiologist reviewing the images and generating a report, and the EP ultimately correlating that information back to the patient (**Figure 6-1**).

Bedside US creates a direct and immediate relationship between patient and EP (**Figure 6-1**). The technology is placed in the EP’s

FIGURE 6-1. The paradigm of bedside US. The workflow of traditional US using the Radiology Department (blue circle with red arrows) is a multistep process that may take hours to days to complete. Bedside US (double yellow arrow) establishes an immediate and direct interaction between patient and physician. (Courtesy of Christopher Moore, MD, RDMS, RDCS.)

hand for both image acquisition and interpretation. The EP can immediately synthesize US findings with clinical and laboratory data to paint a more complete diagnostic picture. A patient’s condition can change on a moment’s notice in the ED. US is a dynamic tool that can be used swiftly and serially throughout a patient’s course.

INDICATIONS

The primary indications of emergency US have traditionally included: cardiac US for the presence of pericardial fluid and for cardiac activity; abdominal US for the identification of free peritoneal fluid; aortic US for abdominal aneurysms; biliary US for the detection of gallstones and cholecystitis; renal US for hydronephrosis and nephrolithiasis; and pelvic US for the identification of an intrauterine pregnancy and the exclusion of an ectopic pregnancy (**Table 6-1**).¹¹⁻¹³ Basic emergency US has operated on the binary premise that emergencies are to be included or excluded by this diagnostic tool. The boundaries between primary and secondary indications have blurred, and the yes/no equation for the evaluation of emergencies has matured.

The list of indications for present-day emergency US is long and continually expanding (**Table 6-1**).¹¹⁻¹³ Another common indication is the evaluation of deep vein thrombosis. Lung US can be used to

TABLE 6-1 The Indications for Emergency Ultrasonography

Primary Indications	Secondary Indications	Procedural Indications
Abdominal	Abscess	Arthrocentesis
Aorta	Deep vein thrombosis	Foreign body localization
Biliary	Gastrointestinal	Lumbar puncture
Cardiac	Genital	Nerve blocks
First trimester pregnancy	Lung	Paracentesis
Renal	Musculoskeletal	Pericardiocentesis
	Ocular	Thoracentesis
	Shock	Transvenous pacer placement
	Other	Vascular access
		Other

diagnose a pneumothorax, pleural fluid, and interstitial lung diseases. US can be used for the evaluation of subcutaneous abscesses, peritonsillar abscesses, deep-space abscesses, and abdominal abscesses. Ocular US can be used to identify a retinal detachment, lens dislocation, vitreous hemorrhage, and foreign bodies and in optic nerve sheath assessment for increased intracranial pressure. Hypotensive patients or those in shock may be evaluated by US of the inferior vena cava and internal jugular veins to estimate central venous pressure. Gastrointestinal US is used for the identification of appendicitis, pyloric stenosis, and other conditions. Genitourinary US is used to look for testicular or ovarian torsion, intrauterine pregnancy, and ectopic pregnancy. Musculoskeletal US is used to diagnose joint effusions, tendinopathy, and fractures. Procedural US is used for guided assistance of vascular access, paracentesis, thoracentesis, pericardiocentesis, arthrocentesis, lumbar puncture, foreign body removal, nerve blocks, and other procedures.

ULTRASOUND PHYSICS

SOUND

Sound is a variation in pressure traveling through a medium, and it is described as a wave. We commonly understand the sound of our vocal communication to travel through air. Sound can also travel through fluid and solid structures. Pressure variations produced by sound waves mechanically displace or oscillate the particles of the medium. This oscillation produces cycles of higher and lower densities, or compression and rarefaction, respectively. Sound waves differ from water waves in that they are longitudinal, meaning the cycles of compression and rarefaction travel in the same direction as the wave. Imagine an analogous spring coil with a force exerted into its length. A wave, or region of compression, will pass down through the coil in a longitudinal or parallel fashion (Figure 6-2). It is important to have an understanding of the terms that describe sound waves as described in the following sections.

FREQUENCY AND PERIOD

Frequency is the number of cycles of pressure variation per 1 second. A single cycle begins at a baseline of absent sound, increases to a maximum value (i.e., compression), decreases to a minimum value (i.e., rarefaction), and returns to baseline (Figure 6-2). Frequency is measured in hertz with a unit of cycles per second and corresponds to the pitch or tone of a sound. The upper acoustical frequency of human hearing is approximately 20,000 hertz, beyond which is considered “US.” Diagnostic US frequencies are generally in the range

FIGURE 6-2. The longitudinal US wave. A force exerted in a parallel fashion along a coil will produce regions of compression and rarefaction. The particles of a sound wave vibrate in the direction the wave travels to create areas of high and low density and pressure. A sound wave is depicted as a classic waveform with peaks representing compression and valleys representing rarefaction.

FIGURE 6-3. The characteristics of an US wave. Period is the duration in time of a single cycle of a wave. Wavelength is the distance in space. Amplitude measures the wave's variation (i.e., height) from baseline.

of 1 million to 10 million hertz or megahertz (MHz). US transducers operate on either the “low” or “high” end of this frequency spectrum, although for each transducer, frequency can be adjusted within a limited range. Frequency is a principal determinant of the resolution and penetration of an image.

Period is the time required for one cycle to occur. Thus, it is the inverse of frequency (Figure 6-3). In ultrasonography, period is typically measured in microseconds (μ s).

WAVELENGTH AND PROPAGATION SPEED

While period measures the duration in time of a single cycle, wavelength measures the distance in space of a single cycle (Figure 6-3). Wavelength is related to the propagation speed and the frequency of a wave. It is represented by the following equation: wavelength = propagation speed \div frequency.

Propagation speed is the velocity at which sound travels through tissue. An average speed through soft tissues of 1540 m/s is generally assumed in basic US. Newer US machines incorporate the propagation speeds of different tissues to provide enhanced imaging.

AMPLITUDE, OUTPUT, AND BIOEFFECTS

Amplitude is a measure of the height or maximum variation of a wave from baseline (Figure 6-3). While frequency corresponds to the pitch or tone of a sound, amplitude is the “loudness” or volume of a sound. This correlates to the brightness of the image. Adjustments of the US machine's output affect the amplitude. Changing the gain produces a similar effect on received echoes. It is preferable to alter brightness on the back end with gain, rather than subject the patient to increased output. Diagnostic US has proven to be exceedingly safe. Concerns do exist over possible thermal and mechanical adverse bioeffects.¹⁴ EPs should strive to perform studies in the shortest time frame, at the lowest output possible, and in-line with the safety acronym ALARA (*as low as reasonably achievable*).

PULSED ULTRASOUND

The earliest US machines produced a continuous stream of US waves. Today's machines release pulses or packets of waves, that is, a few cycles of US at a time. The repetitive pulses are separated by gaps of no sound. Machines can generate pulses of varying duration, frequency, and fraction of time with respect to the soundless gaps. Pulsed US has been essential in the development of advanced imaging.

FIGURE 6-4. The axial resolution of structures. Blue curves represent the transmitted US beam. Red and black curves represent the returning echoes of the superficial and deep structures, respectively. Increasing the frequency shortens the wavelength and improves the axial resolution.

AXIAL RESOLUTION

Axial resolution refers to the ability of the US machine to distinguish two separate structures that lie on top of one another and in a parallel plane to the US beam (**Figure 6-4**). As viewed on the screen, this is one structure on top of another. The structures must produce two separate echoes for each to be recognized as distinct. The smaller the wavelength of the transmitted US beam, the closer in position can be the two tiny distinguishable structures. The size of the wavelength can be decreased by increasing the frequency of the US beam. Increasing the frequency delivers greater axial resolution. However, a sacrifice is seen in penetration because of increased attenuation at higher frequencies.

LATERAL RESOLUTION AND FOCUS

Lateral resolution refers to the machine's ability to distinguish two separate structures that lie side-by-side in a plane perpendicular to the US beam (**Figure 6-5**). As seen on the screen, this is one structure to the side of another. Lateral resolution is a function of the beam width. The narrower the beam, greater is the ability to produce separate echoes for two adjacent objects. Focusing narrows an US beam at specific depths. The focal zone is the narrowest part of the hourglass-shaped US beam. Focusing can be achieved automatically by the machine or manually by the operator. One focal zone or multiple focal zones can be set at specific depths to narrow the beam for optimal lateral resolution.

TEMPORAL RESOLUTION

Continuous US scanning is actually a collection of still frames displayed rapidly over time. US machines produce numerous frames per second as the scan beam is transmitted over and over again

FIGURE 6-5. The lateral resolution of structures. Blue curves represent the transmitted US beam. Black curves represent the returning echoes. The structures must be able to produce separate echoes for the US machine to distinguish them. Focusing of the beam width improves lateral resolution.

through the tissue. The number of frames per second is known as the frame rate. The greater the frame rate, the better is the temporal resolution and the smoother the moving image appears. High frame rates are particularly important for scanning moving structures such as the heart. Employing additional functions such as Doppler scanning may limit the machine's ability to produce high frame rates.

ECHOES

Diagnostic US is predicated on sound waves not only transmitting through tissues but also reflecting back to the transducer (**Figure 6-6**). At an interface of two different tissues, the acoustic impedance of the tissues determines the proportion of transmission and reflection. Acoustic impedance is a measure of a tissue's resistance to sound penetration (i.e., density \times propagation speed). Acoustic impedance is high in "hard" tissues such as bone, lower in visceral organs, and negligible in fluid. Reflection of an echo is a function of the difference between the acoustic impedance of two adjacent tissues. For instance, when a sound wave travels from soft tissue to bone, a significant proportion of the wave will reflect back to the transducer and a minimal amount will transmit through the bone for imaging of deeper structures.

When an US beam travels through parenchymal tissue without interfaces of homogenous acoustic impedance (e.g., liver), imaging is generated not by reflection but rather by scatter. Scattering occurs when a sound wave encounters particles smaller than its wavelength

FIGURE 6-6. The echoes produced as the US beam penetrates tissue. The transmitted beam (orange) attenuates as it penetrates. A reflected echo (green) is produced at an interface. Refraction (purple) and scatter (brown) contribute to attenuation. Scatter produces the imaging within homogenous tissue.

or objects with rough and irregular surfaces. An analogous effect is seen when light is shone through fog. There is some transmission and reflection of the light, but it is the scattering of light that reveals the mass of fog.

In order for an US machine to generate an image, it must determine not only the intensity of the returning echo but also the location of the reflecting structure (i.e., reflector). With a given propagation speed (i.e., velocity of sound through tissue), the machine uses the travel time of the sound wave to calculate the distance the reflector sits from the transducer. The longer the travel time, the deeper is the reflector or structure.

ATTENUATION

As sound waves propagate through a medium, they start to lose amplitude and intensity, or attenuate (Figure 6-6). Attenuation is a result of absorption, reflection, refraction, and scattering of the US wave. Absorption is the conversion of sound to heat as the wave passes through tissue and accounts for the vast majority of attenuation. Absorption has very limited clinical effect for diagnostic US but is the basis of therapeutic US. Reflection is the “echoing” of the wave back to the transducer. Refraction and scattering are the redirection of waves upon encountering certain interfaces.

ULTRASOUND TRANSDUCERS (OR PROBES)

There are many types of transducers that vary in size, shape, construction, transmitted frequency, and function (Table 6-2). Transducers can be expensive and are at risk for damage in a busy ED. Transducers are often dropped and cords frequently run over by the wheels of the US machine. Creative solutions to prevent damage to dangling cords have been developed (Figure 6-7). The expense of replacing transducers should be factored into any warranty and maintenance considerations. Many US manufacturers offer multi-port transducer connections that allow a number of transducers to be connected at once, each activated by the push of a button. Limiting the connecting and disconnecting of transducers decreases the chance of damaging fragile connector pins.

Transducers are the link between the US machine and the patient. The essential component of the transducer for generating an image is the piezoelectric element. The piezoelectric principle states that when an electrical voltage is exerted upon certain materials, a mechanical pressure or vibration will be produced. A transducer’s piezoelectric elements, or crystals, when vibrated by an electrical voltage will generate a mechanical sound wave. The returning sound wave in turn vibrates the elements, creating an electrical voltage that carries image data back to the US machine.

FIGURE 6-7. The preservation technique for transducer cords. Segments of a coiled garden hose are sliced along their length and placed around the middle portion of a transducer cord. This prevents damage from the cart wheels running over dangling cords.

AUTOMATIC SCANNING

Transducers are constructed of numerous elements arranged along the width of the transducer. Unlike a flashlight that emits a single continuous beam of light, the US beam is a composite of pulsed firings of the elements. Automatic scanning is the electronic activation of the elements or arrays of crystals to generate a beam for a cross-sectional image. Two types of automatic scanning currently employed by transducers are sequenced array and phased array scanning.

SEQUENCED ARRAY SCANNING

Sequenced array scanning involves the sequential firing of groups of elements across the transducer assembly (Figure 6-8). One scan

TABLE 6-2 Common Types of US Transducers Used in the ED

Transducer type	Vascular	Abdominal	Endocavitary	Cardiac
Transducer shape				
Type of scanning	Linear sequenced	Curved sequenced	Microcurved sequenced	Phased array
Transducer frequency	High	Low	High	Low
Megahertz (MHz)	7–10	2–5	7–100	2–5

FIGURE 6-8. The basic types of transducers. Linear sequenced and curved sequenced array transducers transmit beams in a sequential fashion following the shape of the transducer head to produce rectangular and pie-shaped images, respectively. The beams of phased array transducers are steered by slight delays in the firing of the elements to produce a pie-shaped image.

line after another is generated along the width of the transducer. Linear transducers are flat-topped and produce a rectangular beam made up of parallel scan lines. Curved transducers transmit scan lines similarly, but following the curve of the transducer, and create a sector- or pie-shaped image. The elements are fired rapidly, and multiple frames of cross-sectional images are produced per second.

PHASED ARRAY SCANNING

Phased array transducers generally have a narrow flat-topped footprint. The tightly packed elements are electrically activated as a single unit, but with a slight time lag between each element, resulting in an angling of the pulse direction. The electronic activation and angling of each subsequent pulse are slightly changed. The resultant composite beam is a sector- or pie-shaped (Figure 6-8).

TRANSDUCER TYPES

The typical arsenal of transducers for emergency US includes a low-frequency curvilinear or phased array transducer, a high-frequency linear transducer, and an endocavitary transducer (Table 6-2). Numerous other types of transducers are manufactured. It is worthwhile to evaluate the options available before purchasing a transducer.

■ CONVEX TRANSDUCERS

Convex or curved transducers are low-frequency transducers that produce a sector-shaped image by sequenced array scanning. These are commonly used in EM. They are useful for most US examinations of the torso. The resolution of these transducers is inferior to that of linear transducers, but the greater penetration allows for imaging of relatively deep structures (e.g., aorta, gallbladder, liver, kidneys, heart). Microconvex transducers have a similar but smaller footprint with a tight curvature that allows for easier use between adjacent ribs.

■ PHASED ARRAY TRANSDUCERS

Phased array transducers are low-frequency transducers made for echocardiography and general imaging of the torso. These transducers have a small flat footprint ideal for maneuvering between the ribs and imaging the heart.

■ LINEAR TRANSDUCERS

Linear transducers are high-frequency transducers that are ideal for imaging superficial structures. They are generally wide, flat-topped, and produce a rectangular image by sequenced array scanning. These transducers are useful in the ED for imaging of blood vessels and guided line placement, skin abscesses, musculoskeletal pathology, pneumothoraces, ocular and testicular pathology, and a host of other superficial parts.

■ ENDOCAVITARY TRANSDUCERS

Endocavitary transducers are high-frequency transducers that have elements arranged in a tight curve at the end of a long handle. They are designed primarily for vaginal insertion and high-resolution imaging of the female reproductive organs. These transducers can be used for US-guided vascular access if no other high-frequency transducer is available. The small footprint and room afforded by the handle may even prove superior to a linear transducer in some instances. The transducer can be used in a patient's mouth for the evaluation of oral and pharyngeal pathology, such as a peritonsillar abscess.

FREQUENCY AND TISSUE HARMONIC IMAGING

Transducers may differ in inherent frequency. The frequency of each transducer can be adjusted within a narrow range of generally a few megahertz. Lowering the frequency may be beneficial if a greater depth is required to view pertinent structures. Conversely, increasing the frequency may improve visualization if a finer resolution is desired more than a deep penetration.

Tissue harmonic imaging is another means of enhancing US scanning. US echoes return from tissues in multiples of the transmitted frequency. The machine can filter out the transmitted frequency and focus on receiving the second harmonic frequency (i.e., twice the transmitted frequency). The returning harmonic beam is narrower than the beam of the fundamental frequency, and hence, lateral resolution is improved. Artifacts and distortions are also reduced with harmonic imaging.

COUPLING MEDIUM

Acoustic gel is the coupling medium used in diagnostic US. The gel obviates any air between the transducer and the patient to improve US beam transmission. Apply the gel across the footprint of the transducer or onto the patient's skin. A good rule of thumb is that too much gel is preferable to too little.

ULTRASOUND MACHINE INSTRUMENTATION

An US machine is made up of numerous components (Figure 6-9). The imaging system hardware consists of a beam former, signal processor, and image processor. The console allows the user to interface with and manage the imaging. The monitor screen provides for black and white as well as color viewing of the imaging. Transducers, single or multiple, have connecting ports onto the machine. Archiving tools, such as a printer or digital storage media, are available standard or as options. The following sections review the key functions that an EP should know when performing US examinations.

CONSOLE

The US console generally consists of a keyboard for data entry and numerous knobs, buttons, dials, and toggle switches for manipulating the images. Carefully read the user's manual or undergo a detailed operations briefing by the manufacturer's application

FIGURE 6-9. Components of a typical US machine.

specialist after purchasing a new machine. While there are many functions that are universal to US machines, they each have their proprietary functions.

There are numerous additional functions on the console. Magnify images with the “zoom” function. The “measure” button activates calipers that are moved with the trackpad or rollerball. This allows for precise measurements to the millimeter. Adjust the dynamic range to produce effects similar to modifying the contrast of a photograph. Other functions include gray-scale mapping, edge, and persistence for image alteration. A dual screen function displays two side-by-side imaging fields. Function keys can be set for easy access to commonly performed tasks.

GAIN

Gain is the US analog to the volume control on a radio. It alters the returning echo to amplify its intensity. Gain is measured in decibels and relates to the brightness of the image. Machines generally have a knob that can be dialed to adjust the gain, increasing or decreasing the overall brightness of the image (**Figure 6-10**).

Time gain compensation (TGC) allows for adjustments of gain at specific depths. Most TGC controls are comprised of a collection of sliding knobs arranged in a column (**Figure 6-11**). The knobs at the top of the column correspond to the near field, and those at the bottom correspond to the far field. The intensity of the beam is attenuated or dampened as an US beam penetrates to greater depths. TGC allows compensation for attenuation. For general abdominal imaging, arrange the sliding TGC knobs with a slope of increasing gain

at greater depths. Use TGC to increase or decrease brightness at discreet depths of the image. Decreasing the gain can improve visualization to compensate for the artifactual brightness seen deep to a fluid-filled structure.

DEPTH

The depth of the field of view can be adjusted by a turn of a dial or toggle of a switch. Depth is conventionally measured in centimeters. Hash marks along the side of the image denote units of distance. Depth adjustments alter the penetration of the imaging beam and allow the user to appropriately “magnify” the organ or region of interest (**Figure 6-12**). The organ of interest will appear too large and its deepest portion may be cut off the screen if the depth is set too shallow (i.e., overmagnification). The organ of interest will appear too small in the near field with wasted space in the deeper regions if the depth is set too deep (i.e., undermagnification).

PATIENT DATA ENTRY

All machines allow the entry of demographic information about the patient and the US examination. The patient data entry screen presents numerous fields that can be filled by typing on the keyboard. These fields commonly include patient name, medical record number, date of birth, and a comments section, to name a few. Functions often available on this screen are examination and transducer selection.

FIGURE 6-10. Gain adjustments brighten and darken the US image. These images of a kidney display a gain setting that is (A) too low, (B) appropriate, and (C) too high.

FREEZE AND CINE

Most machines allow both still images and video loops to be saved. Hitting the “freeze” button stops real-time continuous scanning. The most recent image is displayed on the screen with a few seconds of images (i.e., cine) available for review. Use the rollerball or trackpad to rewind through the cine memory of frames. This allows the viewing and subsequent saving of the most desired still image. A number of machines can allow the viewing of a loop of images as a video.

PRINCIPLES OF GENERAL ULTRASOUND IMAGING

DIMENSIONALITY

The US beam is flat, and the image displayed on the screen is a two-dimensional slice. Sound transmits through most tissues to allow for visualization of deep structures in the cross-sectional slice. Scanning the beam back and forth stacks multiple two-dimensional slices in a

movie format and provides a sense of spatial orientation. Rotating the transducer 90° and scanning through the perpendicular plane helps to gain a three-dimensional comprehension of structures.

ORIENTATION

Orientation is entirely dependent on how the transducer is placed on the patient. Each transducer has a marker that is a bump, ridge, or indentation. The marker correlates with an indicator on the screen to establish orientation. If the transducer is held with the marker aimed cephalad, the screen indicator is located on the left side of the screen (Figure 6-13). This results in the left side of the image representing the cephalad aspect and the right side the caudal aspect (Figure 6-13). The screen indicator is located on the left side for conventional radiology imaging. Most emergency US examinations require views with the transducer marker aimed to the patient’s head and the patient’s right. The image is displayed with the near field (i.e., closest to the transducer) at the top of the screen and the far field (i.e., farthest from the transducer) at the bottom of the screen.

FIGURE 6-11. Time gain compensation (TGC) controls on an US machine consist of a column of knobs that slide back and forth to adjust the gain at specific depths.

ECHOGENICITY

Fluid is anechoic. The US beam transmits through fluid without any reflected echoes. The echogenic silence is processed to generate black pixels on the screen. Highly reflective structures, such as the diaphragm and pericardium, are termed echogenic or hyperechoic. These structures will produce white imaging. Two structures of the same echo-texture are isoechoic. Less reflective tissue is hypoechoic and appears darker on the screen when comparing two tissues (**Figure 6-14**).

ARTIFACTS

Artifacts are images that do not accurately represent the anatomy in the reflected echo. Imaging artifacts are frequently encountered in ultrasonography. It is important to understand and expect certain artifacts to prevent misinterpretation of the images. Artifacts may also help to appreciate certain structures that would otherwise be less obvious.

SHADOWING

A highly reflective object allows very little of an US beam to transmit through it. Most of the beam is reflected back to the transducer, and the structure is represented as hyperechoic or white on the screen. The US machine interprets the lack of returning echoes deep to a structure that is hyperechoic as the lack of reflection, similar to that seen with fluid. This is seen as a black shadow on the screen (**Figure 6-15**). While shadowing from ribs may obscure deep anatomy, the shadows of gallstones aid in their identification.

A

B

C

FIGURE 6-12. Depth adjustments increase and decrease the penetration of the US beam. These images of a kidney display a depth setting that is: (**A**) too deep at 22 cm, (**B**) appropriate at 10 cm, and (**C**) too shallow at 6 cm.

REVERBERATION

Highly reflective interfaces may result in multiple reflections. Bouncing of the sound beam between the reflector and the transducer can create false echoes known as reverberation (**Figure 6-16**). It can be seen when the sound beam encounters two closely spaced

A

B

FIGURE 6-13. The orientation marker (white arrow) on the transducer corresponds with the indicator on the screen (red arrow).

interfaces, such as the two walls of a needle or the visceral and parietal pleura. The echo reflects back and forth between the interfaces, but with some transmission of the beam back to the transducer each time. These returning echoes generate artifactual reflections on the screen termed reverberation or comet tails (**Figure 6-17**).

MIRROR IMAGE

Mirror image artifacts are generated when an object is located in front of a very strong reflector. Structures seen on the near side of a bright reflector are displayed on the other side of the reflector as well. This is common with the diaphragm. Triangulation of the beam path delays the return time of the echo to mirror a second reflector (**Figure 6-18**). Mirror-image artifact can help to exclude a hemothorax by visualizing the liver or spleen cephalad to the diaphragm (**Figure 6-19**).

ENHANCEMENT

Attenuation does not occur when a sound beam passes through a fluid-filled structure. The beam's high intensity is maintained

FIGURE 6-14. Echogenicity of structures are represented by their brightness on the screen. **A.** Anechoic fluid is black. **B.** Echogenic, or highly reflective, compared with adjacent tissues. **C.** Isoechoic, or same echo-texture, as adjacent tissue. **D.** Hypoechoic, or less echoic (i.e., darker) than adjacent tissues. **E.** Hyperechoic, or more echoic than adjacent tissues.

through the fluid. A strong echo is generated off the posterior wall of the fluid-filled structure. The artifact seen on the screen is a very hyperechoic region deep to the fluid-filled structure that may obscure the actual anatomy (**Figure 6-20**).

MISCELLANEOUS ARTIFACTS

A number of additional artifacts can interfere with imaging. Side lobes are weak beams emitted lateral to the central axis of the scanning beam that may produce false echoes. Section thickness artifact is a result of interfering information from the outside of the flat slice

FIGURE 6-15. Echogenic gallstones are present in the gallbladder. Shadowing is seen deep to the gallstones.

FIGURE 6-16. The two walls (white arrows) of a cylindrical bullet are seen superficially. Reverberation artifact produces an additional false echo (red arrow). Shadowing is seen deep to the bullet.

FIGURE 6-17. Each back and forth reflection between the visceral and parietal pleura (white arrow) results in an echo transmitted back to the transducer. Multiple echoes returning one after another produce echogenic artifacts, each deeper than the next. The artifact resembles a comet tail (red arrow).

FIGURE 6-18. Bright reflectors like the diaphragm (white) can generate mirror-image artifacts. The initial beam (solid arrow) reflects off the diaphragm and then an anatomic structure (A) before returning to the transducer. The machine processes the delay as a signal from a deeper structure along the initial scan line (dashed arrow) and generates an artifact (B) on the screen.

FIGURE 6-19. A mirror-image artifact (white arrow) of the spleen is seen cephalad to the diaphragm. This is distinct from fluid that appears black.

of the scanning beam. Refraction of the beam tangentially off an interface may produce a double image of a structure lateral to the original. Shadowing in the narrow angle of refraction may be seen deep to the interface.

ULTRASOUND MODES

BRIGHTNESS MODE

Brightness mode is commonly referred to as B-Mode. This is the basic scanning mode for US. It displays the standard two-dimensional gray-scale image.

MOTION MODES

Motion mode, or M-Mode, is used to assess moving structures. Activating M-Mode produces a vertical line on the image (Figure 6-21). The line can be moved left or right with the rollerball

FIGURE 6-20. High-intensity echo returns from the posterior wall of the bladder and results in a hyperechoic region of enhancement artifact (white arrow).

FIGURE 6-21. The M-Mode. The B-Mode image is displayed at the top of the screen. A green vertical line is seen over the B-Mode image. The area under the green line is displayed over time at the bottom of the screen. The fetal heartbeat is seen at a depth of 3.6 cm and measured at 153 beats per minute.

or trackpad. The US beam penetrating the tissue along that single line is displayed in a continuous graphical manner on the bottom of the screen (**Figure 6-21**). The x -axis of the display is depth, and the y -axis is time. There will be no variation in the M-Mode display if the line is set upon immobile tissue. Movement along the line, such as a beating heart, allows measurements and rate determinations (**Figure 6-21**).

DOPPLER MODE

Doppler scanning allows the assessment of the presence, direction, speed, and character of blood flow and tissue movement. Doppler takes full advantage of the real-time dynamic nature of US. If an object is moving toward or away from the transducer, the frequency of the reflecting echo will be higher or lower, respectively, than the transmitted frequency. The Doppler shift is the difference between the transmitted and reflected frequencies. The US machine can calculate velocity using the Doppler shift. Turbulence, or the variance in velocity of multiple objects in flow, can be assessed. The complexities of Doppler physics and operations are beyond the scope of this chapter.

EPs can use Doppler in the assessment of deep venous thromboses, testicular or ovarian torsion, compromised vascular flow in the extremities, and inflamed or hypervascular tissues; to differentiate vessels from nonvascular structures for diagnostic and procedural purposes; and for advanced echocardiography.

COLOR DOPPLER MODE

A “C” button on the machine’s console usually signifies color Doppler mode. Activating color Doppler produces a box, or region of interest (ROI), overlying the image. The ROI can be maneuvered over the desired area. The size of the box can be manipulated to be larger or smaller depending on the study being performed. Flow is displayed in a color schematic within the ROI (**Figure 6-22**). Flow toward the transducer is typically red. Flow directed away from the transducer is typically blue. Gradients of red and blue signify the speed of the flow.

PULSED WAVE DOPPLER MODE

Pulsed wave Doppler provides a quantitative assessment of flow velocities. Activating pulsed wave Doppler splits the screen, typically placing the image at the top of the screen and a dynamic graph

FIGURE 6-22. The color Doppler box, or region of interest (ROI), placed over the carotid artery reveals flow in the direction of the transducer (red).

of flow velocities at the bottom (**Figure 6-23**). A small “gate” can be positioned over a specific vascular area to measure flow. The size of the gate can be adjusted, allowing very narrow regions to be accurately assessed. The dynamic Doppler graph displays time on the x -axis and velocity on the y -axis. Movement toward the transducer is depicted as a positive velocity deflection. Movement away from the transducer is depicted as a negative deflection.

POWER DOPPLER MODE

Power Doppler is another method of displaying blood flow or tissue motion (**Figure 6-24**). It uses the same ROI box as color Doppler, but with only one shade of color. Power Doppler is very sensitive in identifying the presence of flow but does not reveal its direction. It is advantageous in identifying low flow states and subtle tissue motion and imaging small or deep vessels.

IMAGE ARCHIVING

There are numerous ways to archive US images. Still images can be sent to printers for hard copy archiving. Thermal printers are relatively small and can be attached to the US cart. The gray-scale

FIGURE 6-23. The pulsed wave Doppler mode. A Doppler gate is placed over the center of the carotid artery. Flow is displayed in active graphical format at the bottom of the screen. Positive deflections indicate systolic flow in the direction of the transducer.

A

B

printouts are fine reproductions of the image but are at risk for degradation over time.

Digital archiving allows users to save both still images and videos with a far reduced need for physical storage space. Examinations can be saved to hard drives built into the US machine or to peripheral devices. Machines today offer many options for peripheral storage including compact discs, digital video discs, external drives with universal serial bus connections, and magneto-optical disks.

Specific formats for digital archiving of medical imaging have been developed, in particular the digital information and communication in medicine (DICOM) format. Most US machines today have the ability to save images in the DICOM file format. Picture archiving and communication system (PACS) has been developed for viewing medical imaging in DICOM and other formats. These systems are employed by Radiology Departments for viewing US images, as well as computed tomography, magnetic resonance imaging, plain radiographs, and other imaging modalities. Advantages to saving DICOM images on PACS include improved organization, reliability, and the ability to transmit remotely.

ULTRASOUND-ASSISTED PROCEDURES

US-guided procedures are often performed in EM. A general discussion is provided in Chapter 7. More specifics on US-assisted procedures are included with each specific procedure. Sometimes, the EP does not have enough hands to hold the transducer and perform the

A

B

FIGURE 6-25. The Echosupport device. **A.** The device. (Courtesy of Vygon SA, France) **B.** Photo of the device being used on a patient. (Used with permission from reference 15.)

procedure. Assistants are not always available to hold the transducer in position. A novel device is the Echosupport (Vygon SA, France).¹⁵ It is a reusable, malleable, and sterilizable device (**Figure 6-25**). One end attaches to the patient's bed by a screw clamp. The other end securely holds the US transducer in position.

SUMMARY

US is fast becoming a commonly used modality in EM. All EPs should become familiar with US as it will soon become the standard of care for patient evaluation, patient management, and

procedural guidance. Take the time to investigate the various options available for machines, transducers, and accessories. A thorough understanding of the functioning and features of an US machine is essential before making clinical decisions. Training is readily available through US fellowships, continuing medical education courses, and US manufacturers.

Ultrasound Assisted Procedures

Jehangir Meer and Brian Euerle

INTRODUCTION

Emergency Physicians commonly perform invasive procedures. These procedures have traditionally been taught using surface landmarks, with the assumption that anatomy is reliably similar from patient to patient. The increasing use of ultrasound (US) to assist in procedural guidance has demonstrated this is not the case. Using US to assist

TABLE 7-1 Common ED Procedures that Use US Assistance or Guidance

Body region	Procedures
Abdomen and pelvis	Paracentesis Suprapubic bladder aspiration Suprapubic bladder catheterization
Airway	Endotracheal intubation
Bones and joints	Arthrocentesis Closed fracture reduction Fracture identification Joint dislocation Joint reduction
Chest	Pericardiocentesis Thoracentesis Cardiac pacing (transvenous and transthoracic)
Ear, nose, and throat	Peritonsillar abscess incision and drainage
Nervous system	Peripheral nerve blocks Lumbar puncture
Soft tissue and musculoskeletal	Abscess identification Abscess incision and drainage Foreign body identification and removal
Vascular	Arterial line placement Central venous access Peripheral venous access

with procedures has numerous benefits (**Table 8-1**). It is safer for patients due to reducing complications. US improves patient comfort and satisfaction primarily because fewer attempts are required. The use of US usually decreases the duration of the procedure.

The sonographer must make several decisions prior to beginning a procedure using US. Will the procedure be performed under real-time US guidance, or will US be used only to map the anatomy? Will one person (the sonographer) or two people (the sonographer and an assistant) be necessary? Which US transducer is the most appropriate for the procedure? Should the instrument or needle be imaged using the in-plane technique or the out-of-plane technique? Are needle guides necessary? What is the ideal location of the US machine in relation to the sonographer and patient? These general questions must be kept in mind when using US for invasive procedures and are discussed below.

This chapter reviews basic information regarding the use of US to assist or guide procedures in the Emergency Department (ED). US can assist in many commonly performed ED procedures (**Table 7-1**). The specific US technique for a procedure is described in the chapter for that procedure.

GUIDANCE VERSUS MAPPING

US can be used in one of two ways for procedural assistance: the dynamic technique or the static technique. The dynamic technique is also known as US guidance. **The sonographer uses US guidance in real time during the procedure to survey the anatomy, to confirm a diagnosis, and to visualize the needle or instrument as it enters tissue and reaches the target.** The static technique is also known as US mapping. **The sonographer uses US mapping prior to starting the procedure to map the local anatomy, to confirm a diagnosis, and to mark the site of needle entry. The US transducer is then put away and the procedure performed in the traditional fashion without real-time US.**

The decision between US guidance versus US mapping is influenced primarily by the degree of inherent danger of the procedure. Perform procedures that carry a higher risk or have greater technical difficulty (e.g., central venous access, pericardiocentesis, or foreign body removal) under US guidance. Perform lower risk procedures

(e.g., thoracentesis, paracentesis, or abscess incision and drainage) with US mapping. Another factor is sonographer experience. The experienced sonographer is more technically adept and comfortable doing procedures under real-time US guidance. Novice sonographers who do not have as much psychomotor training and experience may find it easier to use US mapping.

ONE-PERSON VERSUS TWO-PERSON TECHNIQUE

The decision to perform a procedure with one or two people is based on the sonographer's experience and the availability of an assistant. Sonographers with more experience often prefer to guide the US transducer and manipulate the instrument themselves. Their experience and expertise allows them to work with a higher efficiency without an assistant. Assistance during the procedure may not be an option during a busy ED shift, in an ED with single-physician coverage, or in an ED with limited personnel. The sonographer holds the US transducer with the nondominant hand and guides the needle or instrument with the dominant hand for one-person US guidance. This requires a degree of hand-and-eye coordination to maintain continuous alignment of the needle with the US transducer.

Novice sonographers may find it less daunting to use the two-person technique and work with an assistant. The assistant holds the US transducer while the sonographer guides the needle or instrument. The assistant's responsibility is to maintain alignment of the US transducer with the needle during the procedure. The sonographer must maintain good communication with the assistant throughout the procedure to maintain sight of both the needle tip and the target organ on the US monitor screen. This coordination is challenging when using a two-person technique. This is why most US-guided procedures are done by one person holding both the transducer and the needle.

TYPES OF TRANSDUCERS

The following general principle will be helpful in determining which US transducer is the most appropriate for a given procedure. **The higher the frequency of the US transducer, the better the resolution of the structures visualized, but the shallower the maximum depth of view.** In other words, use a high-frequency US transducer for superficial structures and a low-frequency US transducer for deep structures. Low-frequency US transducers include the curvilinear transducer and the phased-array transducer (Table 6-2). High-frequency US transducers include the linear transducer and the endocavitary transducer (Table 6-2). More than one transducer may be required for some procedures. Another factor in selecting the US transducer is its footprint or surface area. A larger footprint is recommended to get a larger scan image unless specific anatomic barriers (e.g., ribs) dictate a smaller footprint. The types of US transducers recommended for some specific procedures are listed in Table 7-2.

ORIENTATION OF THE NEEDLE AND THE TRANSDUCER

Two orientations or approaches are used for US guidance during procedures. The in-plane approach refers to placing the long axis of the needle in line with the long axis of the US beam (Figure 7-1). The out-of-plane approach refers to placing the long axis of the needle 90° to the long axis of the US beam (Figure 7-2). **It is paramount for the sonographer to keep sight of the needle regardless of which approach is used during the procedure.** It is helpful to have the US transducer indicator facing the same side as the

TABLE 7-2 Recommendations for US Transducer Type to Use for Specific Procedures

Transducer type	Procedure
Curvilinear	Endotracheal intubation
	Lumbar puncture
	Paracentesis
	Pericardiocentesis

marker on the top of the US monitor screen to maintain left-to-right alignment.

The in-plane approach allows the entire length of the needle to be visualized as it approaches the target (Figure 7-3). Depth perception is better with this approach. This is a more intuitive approach for some ultrasonographers. The main disadvantage of the in-plane approach is the poor lateral resolution. A needle located to the side of a structure may appear in the same plane as the structure when it is not. **This approach requires precise alignment of the US transducer with the needle. Otherwise, the sonographer can lose sight of the needle.** One procedure best performed with the in-plane approach is a peripheral nerve block.

The out-of-plane approach requires the sonographer to center the target of interest on the US monitor screen. The long axis of the

FIGURE 7-1. The in-plane approach of the needle to the US transducer.

FIGURE 7-2. The out-of-plane approach of the needle to the US transducer.

needle is positioned 90° to the long axis of the US beam, at the center of the long axis of the US transducer (**Figure 7-2**). The short axis view of the needle is visible on the US monitor screen and results in better lateral resolution (**Figure 7-4**). One disadvantage of this approach is the challenge to maintain sight of the needle tip. The sonographer must move the US transducer forward along with the needle tip as it is advanced. **The depth of the needle tip can be misjudged if one is not careful.** This can sometimes result in the inadvertent puncture of the anterior and/or posterior wall of the target structure or another adjacent structure.

FIGURE 7-3. In-plane US view of the needle (arrows).

FIGURE 7-4. Out-of-plane US view of the needle (arrow).

MECHANICAL NEEDLE GUIDES

Needle guides are attachments to the US transducer that keep the needle in a predictable path during the procedure. They are often used by Radiologists for aspiration or biopsy of deep structures. The benefit of using a needle guide is that less hand-to-eye coordination is required to keep the needle aligned with the US transducer during the procedure. The disadvantage of a needle guide is that the path angle is fixed and cannot be changed in the middle of the procedure. A needle guide is not necessary for most of the procedures performed in the ED. It may be disadvantageous since it does not allow “on-the-fly” corrections of the needle path.

GENERAL TIPS FOR GUIDANCE

Always ensure there is a direct line of sight from the procedural field to the US machine (Figure 7-5). The sonographer should not need to turn their head to the side during the procedure to view the US monitor screen. This will greatly improve the sonographer's comfort during the procedure and increase the likelihood of success. Having to turn the head back and forth can result in movement of the needle, movement of the US transducer, an unsuccessful procedure, puncture of incorrect structures, and potential morbidity.

FIGURE 7-5. An example of a good setup with the US machine in relation to the sonographer and the patient.

FIGURE 7-6. Ring-down artifact (arrow) showing the hyperechoic vertical line originating from the needle tip.

Hold the US transducer comfortably in the nondominant hand using a pencil-like grip and maintaining light contact with the patient. It is best to use short controlled movements to maintain visualization when manipulating a needle or other instrument under US guidance. Performing the procedure while seated can also help achieve the fine movements that are required.

Misalignment of the US transducer and the needle is the most common reason for the needle tip not being visualized during the procedure. **Stop advancing the needle if it is not visible on the US monitor screen.** Reposition the US transducer by dragging or fanning it back and forth over the area of the needle until the needle can be seen. Gently rocking or bouncing the needle within the soft tissue can sometimes assist in determining the location of its tip.

Indirect clues can help determine the location of the needle tip if it cannot be seen directly. These include the ring-down artifact (**Figure 7-6**) and the needle shadow artifact (**Figure 7-7**). The ring-down artifact is a bright hyperechoic streak caused by reverberation of the US beam from the highly reflective interface of the needle. The shadow artifact is a hypoechoic line below the needle caused by the needle blocking the US beam. Follow either artifact until the needle can be visualized on the US monitor screen. Continue to follow the needle until its tip is found.

FIGURE 7-7. Needle shadow artifact (arrow) showing the hypoechoic vertical line originating from the needle tip.

Other factors can affect the ability to visualize the needle. Consider these when preparing to perform a procedure. Use the appropriate transducer and depth of field for the procedure. Smaller gauge needles produce smaller artifacts and are more difficult to visualize, especially in cross-section. It is easier to visualize needles perpendicular, or out-of-plane, to the US beam. Needles that are inserted at a shallow angle are typically easier to visualize than those at a steep angle. Consider using extra-reflective needles specific for ultrasonography. Their cost is hard to justify but may be acceptable for teaching. Normal needles are appropriately reflective, and it is difficult to justify these extra-reflective needles clinically. The beveled tip of the needle is easier to visualize than the shaft. The irregular surface of the bevel will reflect the US beam better than the shaft. Insert and advance the needle with a slight “to-and-fro” motion to make it easier to follow the needle path.

SUMMARY

The use of US assistance for procedures is an important skill set in the armamentarium of the Emergency Physician. It allows potentially dangerous procedures (e.g., incision and drainage of a peritonsillar abscess) to be performed in a safer manner due to visualization of the surrounding anatomy. It allows rapid confirmation of a diagnosis at the bedside and results in faster therapeutic interventions (e.g., pericardiocentesis). It usually results in greater patient satisfaction because of fewer attempts being required to successfully complete the procedure. ED ultrasonography can truly be a lifesaving modality when used by trained Emergency Physicians.

Trauma Ultrasound: The FAST and EFAST Scans

Wes Zeger

INTRODUCTION

Evaluation of blunt trauma patients with ultrasound (US) has been described for over 30 years.¹⁻³ Its use in the United States in the early assessment of blunt abdominal trauma patients rapidly increased in the 1990s.¹ It is currently taught as an adjunct to the secondary survey in the Advanced Trauma Life Support (ATLS) course and in residencies.^{1,4} US evaluation of the trauma patient decreases the costs in blunt trauma patients, resource utilization, and time to operative care.^{5,6} There are many advantages to US (Table 8-1).⁷ The focused assessment with sonography in trauma examination is known as the FAST examination and can be completed within 5 minutes.¹ It has replaced the need for a diagnostic peritoneal lavage (Chapter 84) in the initial assessment of all but a few trauma patients.^{8,9} This chapter reviews the technique and interpretation of the FAST examination and the extended FAST, or EFAST, examination.

ANATOMY AND PATHOPHYSIOLOGY

The FAST examination evaluates four anatomic areas or potential spaces for the presence or absence of fluid. These include the hepatorenal recess or Morrison's pouch, the splenorenal recess, the rectovesical or rectouterine space, and the pericardial space. It assumes fluid present represents blood in the setting of trauma. The presence of ascites, bowel fluid, and urine can appear similar using US. These four spaces represent the most dependent areas in the supine patient (Figure 8-1). The volume of fluid accumulation required for visualization by US ranges from 250 to 620 mL.^{10,11} More experienced sonographers can visualize volumes closer to 250 mL.¹⁰

INDICATIONS

The FAST examination is performed after the primary survey. It can be performed in conjunction with ongoing resuscitative efforts. It is indicated when evaluating for the presence of intraperitoneal or

TABLE 8-1 Advantages of Using US

Completed quickly
Decreased cost
Decreased diagnosis time
Decreased resource utilization
Decreased time to operative care
Diagnose degree of fluid in abdomen
Diagnose degree of fluid in pericardium
Diagnose fluid in the abdomen
Diagnose degree of fluid in pericardium
Does not use intravenous contrast
High specificity for fluid
Integrated into primary and secondary survey
Lacks ionizing radiation
No need to move patient
Noninvasive
Performed at bedside
Reduces computed tomography scanning
Reduces diagnostic peritoneal lavage
Safe in children
Safe in pregnancy
Serial repeated exams

pericardial blood in the setting of acute thoracoabdominal trauma. It is also useful in determining resource allocation in the setting of multipatient trauma scenarios.¹

BLUNT THORACOABDOMINAL TRAUMA

The most studied use of the FAST examination has been in adult patients with blunt abdominal trauma. The early diagnosis of hemoperitoneum and/or hemopericardium in the setting of

blunt trauma is critical. The sensitivity of 78% to 90% and the specificity of 98% to 100% for the presence of hemoperitoneum varies depending on the comparison “gold standard.”^{9,12-15} It has been reported to approach 100% sensitivity and 100% specificity in hypotensive patients.^{8,16} One study reported a much lower sensitivity of 42% and specificity of 98%.¹⁷ The difference between these studies was how computed tomography (CT) was used as the gold standard.

Pediatric blunt trauma patients have been less well studied.¹⁸⁻²⁰ However, the FAST examination has shown a similar sensitivity and specificity.²¹⁻²⁴ Its sensitivity approached 90% but its specificity dropped when used to predict the need for operative intervention in pediatric trauma patients.²⁵ Current guidelines recommend evaluation of the pericardial space in adult and pediatric patients with blunt thoracoabdominal trauma.²⁶⁻²⁸ This view of the pericardial space may be more cost effective in hypotensive patients.²⁹

PENETRATING THORACOABDOMINAL TRAUMA

Decreased mortality using US in the assessment of trauma was first described in relation to penetrating chest trauma.³⁰ Its application in patients with penetrating abdominal trauma is less clear. The sensitivity ranges from 48% to 100%, but its specificity remains high at 98% to 100%.^{15,31-34} Assessment of the pericardial space can be helpful in guiding operative intervention in the unstable patient.

CONTRAINDICATIONS

US is a noninvasive diagnostic modality. The FAST examination is contraindicated in the setting of trauma only if it would delay and negatively impact a clinically obvious need for emergent operative intervention. Do not perform and rely on the FAST examination if not properly trained or not supervised by those who have been adequately trained.²⁶

EQUIPMENT

- US machine
- US gel
- US transducer, linear or phased array, 2.0 to 5.0 MHz
- US transducer cover or glove

A complete discussion of US equipment is beyond the scope of this chapter. Decisions regarding machines and transducers depend on the user, cost, and intended applications. The FAST examination can be performed with a good-quality, 2.0 to 5.0 MHz general abdominal transducer.²² Transducers with smaller footprints allow for easier viewing between the ribs. Transducers of 5.0 to 7.0 MHz may better visualize children and small adults.

The US transducer is generally used directly against the patient's skin, with gel between them. Place the transducer in a cover or glove to prevent contamination of the transducer if the patient's skin is covered with blood, feces, urine, vomit, or other substances (Chapter 5). Place US gel in the transducer cover or glove before inserting the transducer. Squeeze out any air in the space between the tip of the transducer and the cover or glove.

PATIENT PREPARATION

Little to no preparation is required to perform the FAST examination. An informed consent is not needed. Tell the patient exactly what will and is happening to prevent them from moving. The US gel is often at room temperature and cold when it touches the skin. Wipe any blood, debris, dirt, and liquids from the patient's skin in

the areas to be scanned. Place the US transducer in a transducer cover or glove if the patient's skin is contaminated with blood, dirt, urine, vomit, or other substances that may contaminate or damage the transducer.

TECHNIQUE

Performance of any US examination assumes the transducer marker orientation is generally cephalad or toward the right relative to the patient. The FAST examination traditionally demonstrates two-dimensional grayscale images of four views reflective of the anatomic potential spaces (i.e., the hepatorenal recess or Morrison's pouch, the splenorenal recess, the rectovesical or rectouterine space, and the pericardial space). View the rectovesical space, the area between the rectum and the bladder, in the male patient. View the rectouterine space, the area between the rectum and the uterus, in the female patient.

The overall examination time should be less than 5 minutes. It frequently can be completed in 1 to 2 minutes. More than one image of the area is required if complete views of the liver or spleen are not visualized with a single image. The order of image acquisition depends on the mechanism of injury. Morrison's pouch is generally imaged first in blunt trauma. This is the area where fluid will most likely first accumulate. This is followed by the splenorenal view, the rectovesical or rectouterine view, and finally the pericardial space. The pericardial space is often imaged first, followed by Morrison's pouch in penetrating trauma, then the remaining two views.

HEPATORENAL RECESS (MORRISON'S POUCH)

The hepatorenal recess is located between the inferior margin of the liver and inferior pole of the right kidney (**Figure 8-1A**). Place the transducer on the midaxillary line at the level of the 8th to 11th ribs (**Figure 8-2A**). Visualize the kidney and liver from the diaphragm to the inferior tip of the liver (**Figure 8-2B**). **Visualize the space between the kidney and liver, including the inferior pole of the right kidney and the inferior liver tip, as fluid tends to accumulate near the tip of the liver first.**³⁵ A black echolucent stripe between the liver and the kidney represents blood and a positive fast exam (**Figure 8-3**). Rib shadows obscuring portions of the image may be prevented by a slight counterclockwise rotation of the transducer so it lies between the ribs.

SPLENORENAL RECESS

The splenorenal recess is located between the inferior margin of the spleen and inferior pole of the left kidney (**Figure 8-1B**). Place the transducer on the posterior axillary line at the level of the 6th to 9th ribs (**Figure 8-4**). **The spleen and kidney should be visualized from the diaphragm to the inferior tip of the spleen.**^{35,36} A black echolucent stripe between the spleen and the kidney represents blood and a positive FAST exam (**Figure 8-5**). Rib shadows obscuring portions of the image may be prevented by a slight clockwise rotation of the transducer so it lies between the ribs.

RECTOVESICAL OR RECTOUTERINE POUCH

The rectovesical or rectouterine space represents the most inferior-posterior reflection of the peritoneum. Place the transducer just superior to the pubic ramus (**Figure 8-6**). The transducer can be oriented in either the sagittal or transverse plane. View the rectovesical space (**Figures 8-6A and 6B**) or the rectouterine space (**Figures 8-6C and 6D**) in both the sagittal and transverse planes.

A black echolucent stripe represents blood and a positive FAST exam (**Figures 8-7 and 8-8**).

PERICARDIAL SPACE

Fluid accumulates initially in the inferior-posterior portion of the pericardial space in the supine trauma patient. The transducer and screen image orientation are different than traditional echocardiographic views. Place the transducer with the marker oriented toward the patient's right and the tip of the transducer aimed toward the patient's left shoulder (**Figure 8-9**). Use the liver as an acoustic window and increase the depth of the US beam to increase image quality. Fluid will initially accumulate near the top of the US image, representing the inferior portion of the pericardial space (**Figure 8-9 inset**). Visualize the inferior and superior areas of the pericardial space. A black echolucent stripe in the inferior or

superior areas of the pericardial space represents blood and a positive FAST exam (**Figure 8-10**).

ALTERNATIVE TECHNIQUES

The incorporation of thoracic imaging coupled with the traditional FAST examination has been referred to as an extended FAST, or EFAST, examination. The additional imaging assesses for the presence of a hemothorax or a pneumothorax.³⁷⁻⁴² A hemothorax is best assessed by visualizing the inferior-posterior aspect of the plural cavity in the supine patient (**Figure 8-11**). As little as 20 mL of blood may be visualized.³³ This area is often visualized in routine views of Morrison's pouch but may require moving the US transducer superior one intercostal space. The lung edges are not normally visualized on US. The lung can be seen "floating" in fluid in the presence of a hemothorax (**Figure 8-11B**). Another sign suggestive of a hemothorax is the "spine" sign (**Figure 8-11B**). The portion of the thoracic spine above the diaphragm can be easily visualized with US. The thoracic spine is not normally well visualized on US superior to the diaphragm (**Figure 8-11C**).

A pneumothorax has distinct findings using US. There is an absence of lung sliding. There are no comet-tail artifacts or B-lines. There are no lung pulsations with respiration. There may be one or two lung points, as described below.

A pneumothorax is best assessed in the supine patient with a curvilinear, linear, or phased-array transducer. A high-frequency

A

B

FIGURE 8-4. Imaging of the splenorenal recess. **A.** US transducer placement with corresponding US screen image. **B.** View of the US beam (green) as it passes through the spleen and kidney.

linear transducer used to image vascular structures is ideal but not required. Sensitivities and specificities range from 59% to 96% and 98% to 99%, respectively, depending on the gold standard.⁴³⁻⁴⁵ Place the transducer on the anterior chest wall in the area bounded by the anterior axillary line, clavicle, nipple, and sternum. This position roughly correlates to the third or fourth interspace.

Start with the transducer on the midclavicular line between the nipple and the clavicle. Move the transducer within the area to obtain the best image possible. Position the transducer perpendicular to adjacent ribs to visualize the intercostal space (**Figure 8-12**). Visualize the interface between the parietal and visceral pleura as a hyperechoic white line. Visualize the normal sliding (i.e., to-and-fro movement) of the pleura on each other during respirations (**Figure 8-12A**). The interface between the two pleura is known as the “sliding-lung” sign and is absent in a pneumothorax. Comet-tail

A

B

FIGURE 8-5. A positive FAST exam of the splenorenal recess. **A.** A black echolucent fluid stripe. **B.** A normal scan for comparison.

artifacts are white hyperechoic reverberation artifacts visualized deep to the pleural line. Air present between the parietal and visceral pleura prevents visualization of lung sliding and comet tails in a pneumothorax.

Use M-mode to visualize the “sea-shore” sign (**Figures 8-12A and 8-12B**). Visualize slightly wavy and parallel lines from the thoracic wall over an echogenic line (i.e., the pleural line) under which is a sandy pattern produced by the lung parenchyma. The parallel lines at the top of the screen represent the waves of the “sea.” The sandy pattern at the bottom of the screen represents the “shore.” Together, they form the “sea-shore” sign. The echogenic line between the “sea” and the “shore” represents the pleural lines. **The “sea-shore” sign indicates a normal chest wall–lung interface.** Air interposed between the chest wall and lung forms parallel horizontal echogenic lines and the loss of the “sea-shore” sign (**Figure 8-12C**).

The lung point is pathognomonic for a pneumothorax.⁴⁶ The lung point is the transition between the sliding-lung sign and the lack of the sliding-lung sign (i.e., the edge of the pneumothorax). It is also seen when the air and lung can be visualized in the same US window. **The lung point is a dynamic sign.** It can only be visualized with the transducer fixed and observing the pleura during the entire respiratory cycle. This is 100% specific to confirm a pneumothorax. This may be difficult to visualize. The lung point can be mistaken for blebs, heart–diaphragm interface, heart–lung interface, lung fibrosis, lung scarring, pleural effusions, or severe pulmonary disease.

ASSESSMENT

The interpretation of each of the four views and of the overall FAST examination is classified as positive, negative, or indeterminate.⁴⁷ Positive examinations demonstrate black echolucent

fluid accumulation in any one of the four views. Negative examinations and scans demonstrate no fluid with complete visualization of all structures. Indeterminate examinations are uncommon and occur when fat or bowel cannot be distinguished from peritoneal fluid or if there is incomplete visualization of any of the four views. Women and children may normally have a small amount of physiologic fluid in their pelvis.⁴⁸ This finding may lead to an indeterminate exam in the setting of trauma. Children are less likely to have free fluid in the pelvis despite an intraabdominal injury.^{20,48,49}

AFTERCARE

Save any US images that are used to make clinical decisions. This is for medical care of the patient and later quality assurance purposes. Label the images with the date, patient medical record number, patient name, and sonographer's name. Make any notes of importance on the images.

Multiple algorithms exist for the management of trauma patients.^{1,4} These are differentiated into blunt trauma versus penetrating trauma and hemodynamically stable versus hemodynamically unstable. A positive FAST examination in the hemodynamically stable blunt trauma patient is typically followed with an abdominal CT scan.⁵⁰ A positive FAST examination in the hemodynamically unstable blunt trauma patient indicates the need for emergent operative intervention without further imaging. A positive FAST examination in adult

FIGURE 8-9. Imaging of the pericardial space. US transducer placement for the subxiphoid view with corresponding US image. (RV, right ventricle; RA, right atrium; LV, left ventricle; LA, left atrium.)

patients with penetrating trauma has good correlation with need for a therapeutic laparotomy.³² Management of these patients may vary between institutions. An unstable pediatric patient with a positive FAST examination may not necessarily proceed to laparotomy because the indications for operative management differ between adults and children.⁴

A negative FAST examination needs to be evaluated within the patient's clinical context. A negative FAST exam in the hemodynamically stable or unstable penetrating trauma patient is a reliable screen for the presence of intrapericardial blood. **It is not a reliable screening test for the presence of abdominal injury.**^{18,51,52} A negative FAST examination in the hemodynamically stable blunt or penetrating trauma patient should be followed by serial clinical examinations and a repeat FAST examination or a CT scan.^{31,50,53,54} Continue the work-up when the FAST examination is negative because of false-negative results are possible. A negative FAST exam in the presence of hemodynamic instability has a high sensitivity; consider an extraperitoneal source of bleeding for the instability. Indeterminate FAST examinations require a follow-up alternative diagnostic modality, usually a CT scan.

COMPLICATIONS

Performance of the FAST or EFAST examination has no associated complications. Inaccurate interpretation or inappropriate application of US findings in clinical decision making may complicate

It is visible when the lung and chest wall are in contact with each other. Note the bright echogenic stripe of the pleural interface between the chest wall (“sea”) and the lung (“shore”). A “comet-tail” artifact may be seen with movement of the parietal pleura (red arrow). **C.** The “sea-shore” sign and the pleural interface are absent when a pneumothorax is present. The red arrow represents motion artifact.

TABLE 8-2 Common Errors

Not examining (i.e., fanning through) the depth of an organ
Not examining (i.e., fanning through) the length of an organ
Not performing serial examinations when the patient changes clinically
Not performing serial examinations with vital sign changes
Not realizing that clotted blood is mixed echogenicity
Not realizing the FAST examination cannot differentiate ascites from blood
Not realizing the FAST examination is insensitive for identification of small amounts of fluid
Not realizing the FAST examination is insensitive for retroperitoneal injuries
Not realizing the FAST examination is insensitive for solid organ injuries
Rib shadowing obstructing the view

its use. Its performance should not delay operative intervention if the patient has indications for the Operating Room (e.g., bowel evisceration).⁵⁴ Common US errors are noted in **Table 8-2**.

SUMMARY

The FAST and EFAST examinations are useful adjuncts in the management of blunt and penetrating trauma patients. They can be performed rapidly, are very specific, and can positively impact patient outcomes. Using US has many benefits (**Table 8-1**). Proper training is required to ensure good-quality images and appropriate interpretation. The false-negative rate makes the use of US more appropriate to rule in an injury than rule one out. Continue the work-up of a negative FAST or EFAST examination if the patient warrants it.

Essential Anatomy of the Airway

Divya C. Karjala, Serge G. Tyler, and Isam F. Nasr

INTRODUCTION

A thorough understanding of airway anatomy is essential for the performance of any airway procedure.¹⁻¹⁰ **Untoward events due to a procedure are usually the result of inexperience and/or an inadequate understanding of the regional anatomy.** The anatomy of the airway and airway procedures are no exception. An understanding of the anatomy of the airway will result in fewer attempts at intubation and improved success with fewer iatrogenic misadventures.

GENERAL ANATOMY

The upper airway comprises the nasal and oral cavities, the pharynx, and the larynx. The lower airway consists of the subglottic larynx, the trachea, and the bronchi.⁸ Airway management typically involves the upper airway, which is the focus of this chapter. The anatomy of the pharynx, larynx, trachea, and principal bronchi is depicted in **Figure 9-1**.¹¹

The nares serve as the functional beginning of the airway, namely warming and humidification of air.⁴ The mucosa of the nasal passage is extremely vascular and fragile. It is susceptible to bleeding with minimal manipulation during instrumentation to establish an airway. The nasal blood supply originates from branches of the internal and external carotid arteries. It is wise to consider the use of a vasoconstricting agent, when appropriate, to help avoid epistaxis, which may obscure further attempts at securing the airway. Although patients tolerate nasal intubation better than oral intubation for a longer time, it is more important in an emergency to definitively secure the airway using a straightforward oral intubation. Choose the more patent side of the nasal cavity for instrumentation in patients with nasal septal deviation.⁴

The sensory innervation of the upper airway is provided by branches of several cranial nerves. The mucous membrane of the nose is innervated anteriorly by the anterior ethmoid nerve (i.e., ophthalmic division of trigeminal nerve) and posteriorly by the sphenopalatine nerve (i.e., maxillary division of trigeminal nerve). The tongue is innervated by the lingual nerve on its anterior two-thirds (i.e., a branch of the facial nerve) and posterior one-third by the glossopharyngeal nerve. The glossopharyngeal nerve also innervates the adjacent areas, the palatine tonsils, the undersurface of the soft palate, and the roof of the pharynx.¹

The pharynx is a fibromuscular tube that extends from the base of the skull to the level of the cricoid cartilage. It connects the nasal and oral cavities with the larynx and esophagus, forming the oropharynx, nasopharynx, and hypopharynx. The velopharynx is the region of nasopharynx at the level of soft palate, a common site for upper airway obstruction in awake and anesthetized patients. An awake patient maintains the pharyngeal muscle tone

to keep the airway patent. This tone is lost under general anesthesia, which promotes and causes upper airway obstruction. A chin lift and jaw thrust maneuver increases the tension on the pharyngeal muscles and counteracts the tendency of the pharyngeal airway to collapse. The posterior wall of the pharynx is made of the buccopharyngeal fascia, which separates the pharynx from the retropharyngeal space. Inadmissible advancement of a gastric or tracheal tubes can result in laceration of this fascia and a retropharyngeal dissection.⁴

The trachea measures 10 to 16.5 cm in an average adult.⁴ The trachea is a tubular structure that begins at the level of the fifth or sixth cervical vertebra. It bifurcates at the level of the fifth thoracic vertebra into two primary bronchi. The posterior aspect of the trachea is flat and membranous, while its anterior and lateral aspect is lined by 16 to 20 horseshoe-shaped cartilaginous rings. The primary bronchi subsequently branch into three secondary bronchi on the right and two secondary bronchi on the left. The angle between the primary bronchus and the trachea on the left is more acute than on the right. This is due to the heart being located on the left side. This is clinically significant during aspiration and endobronchial intubations. **The more direct path on the right side due to the obtuse angle of the primary bronchi results in objects (e.g., food, fluid, foreign bodies) being more likely to enter the right lung.** The tracheal mucosa removes waste products by producing and moving mucus toward the pharynx via ciliary action. The trachea is richly innervated from the vagus nerve. This permits a vigorous cough reflex accompanied by hypertension and tachycardia if a foreign body is aspirated.

The inner diameter of the trachea varies between normal adult males and females, measuring about 15 to 20 mm.⁴ The external diameter of a 7.5-mm internal diameter (ID) endotracheal tube is 11.0 mm. **Size must be taken into consideration in selecting an endotracheal tube.** These considerations usually preclude using endotracheal tubes much larger than 7.5 mm ID for normal adult females or larger than 8.0 or 8.5 mm ID for normal adult males.

ANATOMY OF THE LARYNX

The primary functions of the larynx are phonation and airway protection. The innervation of the larynx is relatively simple. The internal branch of the superior laryngeal nerve provides sensation above the vocal cords (i.e., vocal folds). The recurrent laryngeal nerve supplies sensation below the vocal cords. The recurrent laryngeal nerve provides the motor input to the intrinsic muscles of the larynx except to the cricothyroid muscle, which is supplied by the external branch of the superior laryngeal nerve. Bilateral injury to the recurrent laryngeal nerve will result in total airway closure due to unopposed stimulation of the vocal cord adductor (i.e., the cricothyroid muscle).¹

There are three paired and three unpaired cartilages of the larynx.² The paired cartilages are the smaller arytenoid, corniculate, and cuneiform cartilages (**Figure 9-2**). The unpaired cartilages are the larger thyroid, cricoid, and epiglottic cartilages. The hyoid bone is not part of the larynx but has many ligamentous and

FIGURE 9-1. Anatomy of the upper airway as visualized in a midsagittal section through the head and neck.

muscular attachments to the larynx. The cricoid cartilage is signet ring-shaped, as opposed to the C-shaped cartilages of the trachea (**Figure 9-2**). Depression of the cricoid cartilage will put pressure on structures located posteriorly (i.e., the esophagus) because it forms a complete circle. **The application of posteriorly directed pressure on the cricoid cartilage during intubation is known as the Sellick maneuver (Figure 9-3). The Sellick maneuver will not prevent regurgitation from active vomiting. It has been shown to be effective in the prevention of passive regurgitation and subsequent aspiration.**³ The Sellick maneuver can impair insertion of the laryngoscope, an airway introducer, and cause airway obstruction.

The cricoid cartilage is also an important landmark for locating the cricothyroid membrane. The cricothyroid membrane lies inferior to the thyroid cartilage and superior to the cricoid cartilage (**Figure 9-2**). The cricothyroid membrane is usually located at the level of the sixth cervical vertebra. **It is the anatomic location where emergency cricothyroidotomies and recurrent laryngeal nerve blocks are performed.**¹²

The three paired cartilages are located on the posterior aspect of the larynx (**Figure 9-2**). This position renders them vulnerable to

injury during intubation.² It is less likely that these cartilages will become dislocated or otherwise injured by maintaining an anterior insertion of the laryngoscope blade, systematic visualization of the structures, and by not inserting it too deeply during intubation attempts. This is particularly true if a straight laryngoscope blade is used.

The hyoid bone is an important supporting structure of the upper airway. One of the attachments of the hyoid bone to the larynx is the hyoepiglottic ligament located at the base of the vallecula (**Figure 9-4**). This ligament is important because it is where the tip of the curved Macintosh laryngoscope blade is placed to move the epiglottis anteriorly and out of the path of vision during intubation. Another attachment of the hyoid bone to the larynx is the thyrohyoid membrane (**Figure 9-2**). It runs from the inferior border of the hyoid bone to the superior aspect of the thyroid cartilage. The internal branch of the superior laryngeal nerve passes through the thyrohyoid membrane just inferior to the lateral border of the hyoid bone (**Figure 9-2**). The internal branch of the superior laryngeal nerve is superficial at the thyrohyoid membrane and very easily anesthetized with an injection of local anesthetic solution.

FIGURE 9-2. Right anterolateral and posterior views of the skeleton of the larynx. The thyroid cartilage shields the smaller cartilages of the larynx.

AIRWAY EVALUATION

The evaluation of the airway should always start with a thorough history. **An airway history should be conducted, when feasible, prior to the initiation of airway management in all patients.** It should include whether the patient has ever required intubation and if there was any difficulty. Additional history should focus on the patient's dentition, surgery of the airway, and surgery near the airway. There are many congenital syndromes (Table 9-1) and acquired conditions (Table 9-2) that can complicate airway management.

FIGURE 9-3. The Sellick maneuver. Posteriorly directed pressure is applied to the cricoid cartilage to occlude the esophagus and prevent regurgitation and subsequent aspiration of gastric contents.

Keep these in mind when performing the airway history and physical examination.

External evaluation of the airway is a critical step to a successful intubation and helpful in predicting a difficult intubation. External inspection should identify some obvious problems that may interfere with airway management. These include facial hair that prevents a good mask seal, cervical collars that restrict neck movement, face and/or neck trauma, severe micrognathia, or obesity.

The next steps in evaluating the airway may help to identify patients with potentially difficult airways. The distance between the thyroid cartilage ("Adam's apple") and the inside of the anterior aspect of the mandible is known as the thyromental distance. It should be at least 5 cm or about three large finger breadths in adults.¹ A lesser distance suggests the patient's vocal cords are

FIGURE 9-4. Laryngoscopic view of the larynx.

TABLE 9-1 Selected Congenital Syndromes Associated with Difficult Endotracheal Intubation

Syndrome	Description
Down	Cervical spine spondylolisthesis; large tongue, small mouth make laryngoscopy difficult; small subglottic diameter possible; frequent laryngospasm
Goldenhar (oculoauriculovertebral anomalies)	Mandibular hypoplasia and cervical spine abnormality make laryngoscopy difficult
Klippel-Feil	Neck rigidity because of cervical vertebral fusion
Pierre Robin	Small mouth, large tongue, mandibular anomaly; awake intubation essential in neonate
Treacher Collins (mandibulofacial dysostosis)	Laryngoscopy difficult
Turner	High likelihood of difficult intubation

Source: Modified from reference 1.

TABLE 9-2 Acquired Conditions Affecting the Airway and Associated with Difficult Endotracheal Intubation

Condition	Principal pathologic clinical features of the airway
Acromegaly	Macroglossia; prognathism
Acute burns	Edema of airway that worsens with time; secure airway early!
Angioedema	Obstructive swelling renders ventilation and intubation difficult
Arthritis (rheumatoid)	Temporomandibular joint ankylosis, cricoarytenoid arthritis, deviation of larynx, restricted mobility of cervical spine
Arthritis (ankylosing spondylitis)	Ankylosis of cervical spine; less commonly ankylosis of temporomandibular joints; lack of mobility of cervical spine
Benign tumors (cystic, hygroma, lipoma, adenoma)	Stenosis or distortion of airway
Diabetes mellitus	May have reduced mobility of atlantooccipital joint
Foreign body	Airway obstruction
Hypothyroidism	Large tongue and abnormal soft tissue (myxedema) make ventilation and intubation difficult
Infectious (croup and supraglottitis)	Laryngeal edema
Infectious abscess (intraoral and retropharyngeal)	Distortion and stenosis of airway and trismus
Ludwig's angina	Distortion and stenosis of airway and trismus
Malignant tumors (carcinoma of tongue, larynx, or thyroid)	Stenosis or distortion of airway; fixation of larynx or adjacent tissues secondary to infiltration or fibrosis from irradiation
Morbid obesity	Short, thick neck, and large tongue are likely to be present
Pregnancy	Edema of airway
Sarcoidosis	Airway obstruction (lymphoid tissue)
Scleroderma	Tight skin and temporomandibular joint involvement make mouth opening difficult
Temporomandibular joint syndrome	Severe impairment of mouth opening
Thyromegaly	Goiter may produce extrinsic airway compression or deviation
Trauma (head, face, or cervical spine injury)	Cerebrospinal rhinorrhea, edema of airway; hemorrhage; unstable fracture(s) of maxillae and mandible; intralaryngeal damage; dislocation of cervical vertebrae

Source: Modified from reference 4.

positioned more anteriorly than normal. **Distances less than 5 cm may indicate that visualization of the larynx during intubation may be difficult or impossible due to a lack of space in which to displace the tongue.**

The next step requires the patient to open their mouth maximally. The patient ideally will be in a seated or semisitting position. The distance between the maxillary and mandibular incisors in an average adult is 3 to 5 cm or approximately two large finger breadths.⁵ Limited mouth opening may impair visualization of the airway as well as expose the teeth to damage during intubation.

Adults should be able to flex their cervical spine 35° and extend the cervical spine at the atlantooccipital joint 80° from a neutral position.⁶ This range of neck movement allows for the alignment of the oral, pharyngeal, and laryngeal axes during orotracheal intubation (**Figure 9-5**). **This alignment of the axes provides the greatest chance for a successful intubation.** Evidence suggests slight head extension in infants and young children by placing a rolled towel behind their shoulders better aligns the vision of the glottic and laryngeal axes.¹⁰ Observe the patient's neck for length and thickness. A short, excessively long, or thick neck may indicate difficulty in placing the patient in the sniffing position and aligning the airway axes.

The internal examination should evaluate the patient's dentition, palate, and tongue. Note any protuberant incisors (i.e., buck teeth), loose teeth, broken teeth, dental work, and dental devices. Prominent upper incisors may complicate the insertion of the laryngoscope blade, make laryngoscopy difficult, and predispose the patient to dental trauma. Assess the relation of the maxillary and mandibular incisors during normal jaw closure. Lack of an overbite forces the laryngoscope blade to enter the mouth in a more cephalad direction than normal. This can result in difficulty visualizing the airway. Observe the maxillary and mandibular incisors during voluntary protrusion of the mandible to determine the degree of temporomandibular joint mobility. Determine if the palate is normal, high and arched, or cleft. Determine if the tongue is elevated or larger or wider than normal in comparison to the oral cavity. Any abnormality can make the procedure of orotracheal intubation more difficult.

A common classification used by Anesthesiologists to grade the difficulty of laryngoscopy and intubation involves the identification of the size of the tongue in relation to the tonsillar pillars, the fauces, the soft palate, and the uvula.⁷ **Instruct the patient to open their mouth and protrude their tongue maximally in the sitting position. The patient should not say "ahhh," as this distorts the anatomy and may falsely improve the airway classification.** The Mallampati classification, named after its author, has four grades or classes.⁷ The anterior and posterior tonsillar pillars, the fauces, the soft palate, and the uvula can be fully visualized in class I (**Figure 9-6A**). The fauces, the soft palate, and the uvula can be visualized in class II (**Figure 9-6B**). The anterior and posterior tonsillar pillars are covered by the base of the tongue and not visible. Only the soft palate and the base of the uvula are visible in class III (**Figure 9-6C**). None of the structures are visible in class IV (**Figure 9-6D**). The predictive value of this classification is that during direct laryngoscopy, the entire glottis can be exposed in 100% of class I airways, 65% of class II airways, 30% of class III airways, and 0.1% of class IV airways.⁷

The airway evaluation is imperfect in predicting potential problems, and an airway strategy requires a combination of plans for each patient. Additional evaluation may be indicated in some patients to characterize the likelihood or nature of the anticipated airway difficulty. The findings of the airway history and physical examination may be useful in guiding the selection of specific diagnostic tests and consultation.

FIGURE 9-5. Head positioning for endotracheal intubation. **A.** The normal alignment of the oral, pharyngeal, and laryngeal axes. **B.** Elevation of the head about 10 cm with pads below the occiput, while the shoulders remain on the table, aligns the laryngeal and pharyngeal axes. **C.** Subsequent head extension, at the atlantooccipital joint, serves to create the shortest distance and most nearly straight line from the incisor teeth to the glottic opening.

FIGURE 9-6. The Mallampati classification. **A.** Class I. **B.** Class II. **C.** Class III. **D.** Class IV.

ANATOMIC DIFFERENCES BETWEEN THE ADULT AND THE YOUNG CHILD

There are numerous differences between the airway of an adult and that of a child.^{11,13-15} The head-to-body ratio is larger in the child. This causes the neck to be flexed when the child is supine. Placing a rolled towel under the child's shoulders will correct the flexion. A child has a small mouth with a relatively large tongue as compared to an adult. This can make orotracheal intubation difficult. The presence of adenoidal tissue in the child makes nasotracheal intubation difficult and orotracheal intubation the preferred method.

The anatomic differences between the larynx of an adult and that of a young child are summarized in **Table 9-3** and **Figure 9-7**.¹ The vocal cords are more obliquely inclined in the child. The cricothyroid membrane is very small and narrow. **The most important difference is that the narrowest portion of the infant or young child's airway is below the level of the vocal cords at the level of the cricoid cartilage. The narrowest point of the adult airway is at the level of the vocal cords.** The cricoid cartilage is the only complete cartilaginous ring and the narrowest part of the trachea. An endotracheal tube may therefore pass through the vocal cords of a young child but might not advance past the cricoid cartilage due to normal anatomy. Forcing an endotracheal tube past the vocal cords in a young child may result in trauma to the airway and subsequent tracheal stenosis. Blind nasal intubation is not possible because the child's larynx is located more cephalad at the level of the third or fourth cervical vertebrae and angulated anterior to the glottis. The child's laryngeal inlet is narrow and more susceptible to obstruction. The U-shaped epiglottis and a more acute angle between the epiglottis and glottis cause the aryepiglottic folds to be more in the midline (**Figure 9-7B**).

TABLE 9-3 Anatomic Differences Between the Child's and the Adult's Larynx

	Child larynx	Adult larynx
Size	Smaller	Larger
Shape	Lumen is funnel-shaped with the narrowest part below the vocal cords and within the cricoid ring	Narrowest part of lumen is at the vocal cords
Location	Higher, closer to the tongue base; vertical extent is opposite C3, C4, C5 vertebrae; more anterior	Vertical extent is lower, opposite C4, C5, C6 vertebrae
Epiglottis	Longer, narrower, and "U" shaped; the angle between glottis and epiglottis is more acute; increased chance of airway obstruction (see Figure 1-8)	Shorter and wider
Vocal cords	Angled in relation to the axis of trachea; shorter; more cartilaginous; more distensible; more likely to be injured	Perpendicular to the axis of trachea
Rigidity	The laryngeal cartilages are softer and more pliable	More rigid
Response to trauma	Mucous membrane is more loosely attached and swells more readily when traumatized or infected	Less vulnerable to trauma and infection

Differences also exist in the trachea. Children have a relatively shorter trachea. This makes both right main bronchial intubation and accidental extubation much easier. The narrower diameter of the trachea with smaller spaces between the cartilaginous rings makes a tracheostomy more difficult to perform. Consider using uncuffed endotracheal tubes in children less than 28 days of age to avoid injury and subsequent subglottic stenosis.¹⁶ A correctly sized endotracheal tube should have a leak at 15 to 25 cmH₂O. Using the uncuffed endotracheal tube with a high leak pressure of more than 25 cmH₂O or a cuffed endotracheal tube can cause croup after extubation, an erosion of the mucosa, and/or subglottic stenosis. A cuffed endotracheal tube is recommended for anyone above the age of 28 days.^{10,16-18}

The differences also continue into the chest. The infant thoracic cage is more compliant than that of the older child and adult. This can lead to more effective ventilation. The child's diaphragm is shorter and flatter than in the adult and has a decreased excursion during respiration. The child's relatively narrower airway results in an increased resistance to inspiratory and expiratory airflow. Children are more susceptible to airway edema and mucous plugs obstructing their narrow airway. Children have smaller and fewer alveoli. This results in less surface area for gas exchange compared to adults.

**FIGURE 9-7.** Differences between the adult's larynx (A) and the child's larynx (B).

ULTRASOUND OF THE AIRWAY

Ultrasound (US) is a newer development to evaluate the upper airway anatomy.¹⁹ It is noninvasive, simple, portable, and provides no ionizing radiation. US facilitates the study of the upper airway structures (i.e., thyroid cartilage, cricoid cartilage, epiglottis, cricothyroid membrane, tracheal cartilage, and esophagus). US simplifies the assessment of airway anatomy for difficult intubation, detects upper airway pathology, helps determine endotracheal tube and laryngeal mask airway placement depth, and assesses airway size. US has proven benefit when performing emergency invasive airway procedures (e.g., cricothyroidotomy and tracheostomy). It can be used to predict postextubation stridor. An air column width ratio of 0.8 or less measured with US may predict the occurrence of postextubation stridor.¹⁹

SUMMARY

It is essential for Emergency Physicians to know the anatomy of the airway, especially the differences found in the young child. The airway assessment is an essential element in the preparation to intubate a patient. There may be limited information and time available to perform the full assessment in the Emergency Department. A quick airway assessment in every patient before orotracheal intubation will allow the Emergency Physician to effectively intubate.¹⁴

Basic Airway Management

Christopher J. Russo

INTRODUCTION

Airway management remains one of the most basic and important aspects of Emergency Medicine. The concepts and techniques described in this chapter can be applied in a variety of environments. Understanding the following concepts and having an opportunity to practice them will allow the provision of the most fundamental of all medical care, support of a patient's airway.

The primary purpose of airway management is to facilitate the transport of oxygen to the lungs. Without oxygen, the brain begins to die within minutes.¹ The secondary purpose of airway management is to protect the airway from aspiration or contamination with blood, fluids, or food. Airway management can be as simple as lifting a snoring patient's chin or as involved as awake, fiberoptic-guided endotracheal intubation.

The fundamental importance of airway management is reflected by the fact that much of Basic Life Support taught by the American Heart Association is concerned with this vital function.² **The mission of airway management is "to ensure a patent airway, provide supplemental oxygen, and institute positive-pressure ventilation when spontaneous breathing is inadequate or absent."**³ These three key aspects of airway management warrant repeating. **Ensure a patent airway. Provide supplemental oxygen. Provide positive-pressure ventilation.**

Time is always critical when a patient needs airway support. The body's limited oxygen stores are rapidly exhausted once breathing stops. A healthy individual having maximally breathed 100% oxygen will begin to become hypoxic and have brain injury after 5 minutes of apnea. A sick patient breathing room air will become hypoxic almost immediately upon becoming apneic.¹

Oxygenation and ventilation remain the essential goals of airway management. Inadequate ventilation may occur for a variety of reasons. Spontaneously breathing patients may develop an airway obstruction due to blood, food, secretions, or tissue obstruction from the loss of normal pharyngeal tone. The conscious patient with an airway obstruction will be in obvious distress and is more likely to have an obstruction due to a foreign body, laryngeal edema, laryngospasm, tissue swelling from an infection, or a tumor. The unconscious patient is at risk for aspiration of gastric contents despite spontaneous respirations. Secure the airway of an unconscious patient with intubation (Chapter 18) and mechanical ventilation (Chapter 36).

ANATOMY AND PATHOPHYSIOLOGY

The upper airway includes the nasal, oral, pharyngeal, and laryngeal anatomy and physiology. This highly complex system is responsible for conveying warmed and filtered air to the trachea and lungs while simultaneously allowing for passage of liquids and solids to the esophagus. Phonation is a secondary physiologic function of the larynx.⁴ This highly sophisticated system allows us to drink liquid, eat food, breathe, and talk simultaneously. A profound system of

reflexes is activated to protect the airway integrity if a small drop of liquid or a particle of food enters.⁵

The nasal cavity and the nasopharynx compose the area from the tip of the nose to the palate. The nasal cavity is bounded laterally by the bony framework of turbinates and medially by the nasal septum. This area is highly innervated by the ophthalmic and maxillary branches of the trigeminal nerve. The mucosa of the nasal cavity and the nasopharynx is highly vascular. This high degree of vascularity allows cool air from the environment to be warmed and humidified prior to entering the lungs. **It dictates that care be taken when nasal airways are placed.** It takes very little trauma to the nasal mucosa to cause significant epistaxis. The nasopharynx can be obstructed from congestion due to an upper respiratory infection, mucus, or polyps. The nasopharynx is oriented in an anteroposterior plane. **Insert the nasal airway or nasogastric tube perpendicular to the horizontal axis and not in a cephalad direction.**

The oropharynx extends from the palatoglossal fold down to the epiglottis. The primary structure contained within the oropharynx is the base of the tongue. The anterior two-thirds of the tongue is innervated by the lingual nerve, a branch of the facial nerve. The posterior one-third of the tongue, the tonsils, and the palate are innervated by the glossopharyngeal nerve.⁶ Salivary glands located in the oropharynx can produce a significant volume of saliva and create potential problems for mask ventilation or intubation. Loose teeth can be inadvertently dislodged into the oropharynx and can become hazardous foreign bodies in the airway.

Edentulous patients present a unique set of problems for mask ventilation.⁷ The lack of a maxillary alveolar ridge may allow the face mask to collapse into the airway. Redundant tissue due to lack of teeth tends to collapse into the airway. This makes mask ventilation extremely difficult without a nasal airway or oral airway. An appropriately sized and placed oral airway is the best way to overcome the problem of upper airway obstruction in the unconscious and edentulous adult patient.

The laryngopharynx extends from the epiglottis to the inferior border of the cricoid cartilage. The piriform recesses lie in the pharynx, on either side of the larynx, and the esophagus resides posteriorly. The larynx is positioned at the entrance to the trachea, acts as the sphincter of the pulmonary system, and is made up of nine cartilages to support this function.⁶

There are three paired and three unpaired cartilages. The unpaired cartilages are the cricoid, epiglottis, and thyroid cartilages. The paired cartilages are the arytenoids, corniculates, and cuneiform cartilages. **The cricoid cartilage is the only complete ring in the entire airway.** This presents a unique opportunity for the practitioner to help prevent gastric aspiration. **The cricoid cartilage can be firmly pressed posteriorly to pinch the esophagus against the cervical spine and prevent the passive regurgitation of gastric contents. This is known as the Sellick maneuver.**⁸ **The cricoid cartilage is the narrowest point of the airway in the pediatric patient, while the glottic narrowing is the most narrow point in adults.** The cricoid and thyroid cartilages are the landmarks for identifying the cricothyroid membrane, which is essential in obtaining an emergent surgical airway.

The sensory and motor innervation of the larynx is derived from the vagus nerve.⁶ The superior laryngeal nerve is a branch of the vagus nerve and gives rise to the internal branch. This provides the sensory innervation of the upper larynx. The superior laryngeal nerve gives rise to the external branch, which provides the motor innervation to the cricothyroid muscle (i.e., a vocal cord adductor). The recurrent laryngeal nerve provides the sensory innervation to the larynx below the vocal cords and motor innervation to all other laryngeal muscles.⁶

The trachea is approximately 15 cm long in an adult. It is composed of 17 or 18 C-shaped cartilaginous rings.⁶ **The rings are essential to prevent the trachea from collapsing during the negative intrathoracic pressures generated on inspiration.**

INDICATIONS

The decision to institute airway support must often be made very quickly and frequently without the aid of laboratory results, pulmonary function tests, or radiographic studies. **The decision to institute emergent airway support is usually based on clinical judgment and the signs and symptoms of inadequate oxygenation and ventilation.** The signs of impending respiratory failure are agitation, cyanosis, dyspnea, tachypnea, and use of accessory muscles.⁹ The patient will demonstrate extreme anxiety, audible wheezing or stridor, and aggressive attempts to clear the obstruction in the case of a partial airway obstruction. There may be no audible breath sounds if the obstruction is complete.

Perform a more formal evaluation of the indicators that warrant respiratory assistance if time exists (Table 10-1).¹⁰ The ultimate signs indicating the necessity for airway assistance are hypoxia and hypercarbia. The most common etiologies resulting in the need for airway support are airway obstruction (e.g., food, foreign body, and vomit), cardiopulmonary arrest, drug overdoses, and toxic reactions. Impending ventilatory failure due to congestive heart failure, pneumonia, or severe asthma is a common indication for endotracheal intubation.

CONTRAINDICATIONS

There are no absolute contraindications for basic airway management. The contraindications for the various methods of endotracheal intubation are discussed in subsequent chapters.

EQUIPMENT

- Bag-valve-mask device
- Oxygen source
- Clear face masks, various sizes and shapes
- Oropharyngeal airways, various sizes
- Nasopharyngeal airways, various sizes
- Head strap
- Yankauer suction catheter
- Suction source
- Pulse oximeter
- Tongue blades or tongue depressors
- Water-soluble lubricant or anesthetic jelly
- Cardiac monitor
- Noninvasive blood pressure system

TABLE 10-1 Indicators That Warrant Respiratory Assistance

A-a gradient > 350 mmHg on 100% O ₂
PaCO ₂ > 55 mmHg
PaO ₂ < 60 mmHg on 40% O ₂
Respiratory rate > 35
SaO ₂ < 90%
Vital capacity < 15 mL/kg

Data from reference 10.

TECHNIQUES

PATIENT POSITIONING

The first goal of airway management, regardless of a patient's ability to breathe spontaneously, is the establishment of a patent airway. This may be all that is required in a patient who has an upper airway foreign body or a patient who has suffered a loss of consciousness with loss of pharyngeal tone. **The importance of proper positioning cannot be overemphasized. The success of airway management is predicated on this very basic but often overlooked issue.** Placing the patient in the “sniffing” position, or lateral decubitus position, may correct many upper airway obstructions due to soft tissue impingement.¹¹ **The “sniffing” position is achieved by flexing the cervical spine approximately 15° and extending the atlantooccipital joint maximally (Figure 10-1).**¹⁰ This is the position one subconsciously adopts in order to sniff and smell. **Omit head extension in the patient with cervical spine precautions. The sniffing position can be achieved with the chin-lift and/or jaw-thrust maneuvers.**

Obesity or large breasts on a patient often cannot be effectively managed in a supine position (Chapter 15). The normal sniffing position in an obese person is often not sufficient to relieve an airway obstruction (Figure 10-2A). Place a ramp or shoulder roll under the patient's upper back to achieve the sniffing position (Figure 10-2B).

JAW-THRUST MANEUVER

The jaw-thrust is one of the most basic maneuvers and an initial method of establishing a patent airway.¹² The tongue is attached to the mandible and may fall into the pharynx in the supine patient. **The goal of the jaw-thrust maneuver is to move the tongue away from the palate and posterior pharyngeal wall.** The jaw-thrust maneuver is a two-handed technique that can be used with the face mask and a second person to provide positive-pressure ventilation. Stand at the head of the patient and place fingers on the angles of the patient's mandible bilaterally and displace the mandible anteriorly (Figure 10-3). This maneuver elevates the tongue from the pharynx and allows air to flow unobstructed and posterior to the tongue.

FIGURE 10-1. The “sniffing” position for successful airway management.

FIGURE 10-2. Airway management in the obese patient. **A.** The normal “sniffing” position is inadequate to open the airway. The red line represents the axis of the airway. **B.** A ramp placed under the head and shoulders will achieve the “sniffing” position.

CHIN-LIFT MANEUVER

The chin-lift is another basic maneuver and an initial method of establishing a patent airway.¹² Place the fingers on the inferior surface of the patient’s mandible (**Figure 10-4**). **Do not place any of the fingers on the soft tissues of the submandibular space. This will elevate the tongue and cause further obstruction.** Lift the chin in

FIGURE 10-3. The jaw-thrust maneuver.

FIGURE 10-4. The chin-lift maneuver.

an anterior and cephalic direction. The head may be tilted slightly posteriorly to aid in opening the airway.

NASOPHARYNGEAL AIRWAYS

The majority of airway obstruction occurs in the region of the pharynx.¹³ Use various aids in addition to positioning to overcome obstruction and facilitate effective ventilation. The most commonly used devices are oropharyngeal (oral) and nasopharyngeal (nasal) airways. **Place a large enough airway to bridge the area of soft tissue impingement on the pharynx regardless of which device is chosen.**

Nasal airways (i.e., nasopharyngeal airways or nasal trumpets) are soft rubber, plastic, or silicone tubes that are inserted through the nostril and into the oropharynx just above the epiglottis. Nasal airways are available in numerous sizes (**Figure 10-5**). The proximal end has a flange that rests against the patient’s nares and prevents the nasal airway from slipping backward into the nose and becoming a foreign body in the patient’s airway. The larger the inner diameter, the longer is the tube. The nasal airway is more comfortable for the patient than an oral airway. Nasal airways carry the significant risk that their placement may result in epistaxis.^{3,10} A size 30 or 32 French nasal airway is appropriate for most adults. It can be safely placed in the conscious, semiconscious, or unconscious patient. A nasal airway can be used when an oral airway cannot be placed (e.g., braces, oral trauma, seizures, trismus, etc.). **It is imperative to perform the jaw-thrust and/or chin-lift to prevent the tongue from obstructing the patient’s airway when using a nasal airway.**

The Naso-Flo (Mercury Medical, Clearwater, FL) is a newer type of nasal airway (**Figure 10-5D**). It is available in numerous sizes with and without oxygen ports. Oxygen connects to the elbow port on the proximal end. The oxygen port allows for higher levels of inspired oxygen. Some models are available with end-tidal carbon dioxide connectors attached to the proximal end.

Insertion of a nasal airway is a rapid procedure. Choose the proper size nasal airway by placing the flared end of the airway near the tip of the patient’s nose. The distal end of the nasal airway should be at the external auditory canal. Liberally apply water-soluble lubricant or anesthetic jelly to the nasal airway. Apply a

vasoconstrictor to the patient's nasal mucosa if not contraindicated. Gently insert and advance the nasal airway with the beveled tip against the nasal septum (**Figure 10-6**). This will prevent epistaxis from the tip of the nasal airway getting caught on the inferior or middle turbinate. Insert and advance it along the floor of the nasal cavity adjacent to the septum. Continue to advance the nasal airway completely until the flared end is against the patient's nostril. Rotate the nasal airway 90° so it is concave upward. Slight rotation will often facilitate the passage of the nasal airway if resistance is encountered during insertion. Insert the nasal airway into the other nostril or use a smaller nasal airway if resistance is still encountered. Begin the administration of supplementary oxygen or positive-pressure ventilation with a bag-valve-mask device after insertion of the nasal airway.

Insertion of a nasal airway may be associated with complications. It may cause laryngospasm or vomiting if the device is too long. A nasal airway that is too long may be placed with its tip in the esophagus and result in gastric distention and subsequent aspiration. Nasal mucosal injury upon insertion can cause epistaxis and aspiration of blood.

FIGURE 10-6. Insertion of the nasopharyngeal airway.

OROPHARYNGEAL AIRWAYS

The oropharyngeal airway (i.e., OPA or oral airway) is a semicircular plastic device that holds the tongue up and away from the posterior pharyngeal wall (**Figure 10-7**). They are available in clear, color-coded, and a variety of other styles. Oral airways cause less trauma and are more easily placed than nasal airways. **Use oral airways only in unconscious patients. They may result in laryngospasm or vomiting if placed in a conscious or semiconscious patient.**¹⁴

Oral airways have many uses. The primary indication is to maintain a patent airway. It will prevent the patient from biting, lacerating, or occluding an endotracheal tube. It facilitates oropharyngeal suctioning by removing the tongue from the airway. It will protect the tongue from bites during seizure activity. Oral airways are sometimes used as bite blocks for inserting scopes orally.

The oral airway is often considered an accessory to the use of face mask ventilation after the face mask is difficult to ventilate the patient. This results in delays using an oral airway. Use an oral airway immediately in patients who are edentulous without their dentures, have a history of obstructive sleep apnea, have a nasal obstruction, are obese, or snore. **Use the oral airway in conjunction with the chin-lift or jaw-thrust.**

Insertion of the oral airway is a quick and simple procedure. Choose the proper size oral airway. The correct size is estimated by placing the proximal flange of the oral airway next to the patient's mouth. The distal tip should lie just above the angle of the mandible. An 8.0, 9.0, or 10.0 cm oral airway is appropriate for most adults.¹⁵

Clear the mouth and oropharynx of any blood, secretions, or vomit with a Yankauer suction catheter. Open the patient's jaw with the nondominant hand. Separate the patient's jaws with a "scissors-like" action of the thumb on the lower teeth and the index or middle

finger on the upper teeth. Insert the oral airway curved side down (**Figure 10-8A**). The tip will slide along the hard palate. Insert it until the plastic flange on the proximal end is at the patient's lips. Rotate the oral airway 180° so that its curve follows the curvature of the tongue.

An alternative method is to use a tongue depressor to depress the tongue and then insert the oral airway as described above. The oral airway may be inserted with the curve side upward if a tongue depressor is used (**Figure 10-8B**). Begin administering supplementary oxygen or positive-pressure ventilation with a bag-valve-mask device after inserting the oral airway.

A newer device is the Dual-Air Adjustable Oropharyngeal Airway (NuZone Medical, Spokane, WA) (**Figure 10-9**). It was designed for single use, to provide greater patient comfort, and to improve ventilation. It comes in three sizes. The extra-large size adjusts from 90, 100, and 110 mm. The large adjusts from 70, 80, 90, and 100 mm. The pediatric size adjusts from 50, 60, and 70 mm. They all adjust to half-steps between the major markings. The device can be adjusted in the patient's mouth. The large central opening allows a suction catheter to bypass the tongue and teeth. Each is individually packaged and decreases the possibility of contaminating others. The large opening improves laminar flow and reduces the pressure required for ventilation.

Insertion of an oral airway is not a benign procedure. It can push the tongue posteriorly and further obstruct the oropharynx if the oral airway is not inserted properly. Significant lacerations can occur if the lips or tongue is caught between the teeth and the oral airway. An oral airway that is too long can force the epiglottis closed against the vocal cords and produce a complete airway obstruction. Too small of an oral airway will force the tongue against the pharynx and produce an obstruction.

MASK VENTILATION

The likelihood of success in airway management is often predictable.¹⁶ The ease of mask ventilation and intubation is directly related to anatomy. Anesthesiologists rely on a series of evaluations and classification criteria to help predict the success of airway management. The most widely used classification is the Mallampati classification (Figure 9-6).¹⁷ This evaluation is combined with an examination of the ability to fully open the mouth, body habitus, cervical range of motion, dental structures, neck thickness, temporomandibular joint function, and thyromental distance to help predict the ease or difficulty of airway management.¹⁶⁻²²

A distinction must be made between ease of mask ventilation and ease of oral endotracheal intubation. The two are often correlated but can, at times, be completely unrelated. For example, a patient with a normal body habitus who is in a cervical halo may be very easy to ventilate by mask but impossible to intubate orally via direct laryngoscopy. The obese patient with sleep apnea and a Mallampati class I airway may be very easy to intubate but virtually impossible to ventilate by mask.

Evaluate the presence of spontaneous respirations after achieving the proper positioning. Initiate positive-pressure ventilation if the

patient is not breathing and there is no evidence of a foreign body. The Heimlich maneuver (Chapter 224) is the method of choice in the awake patient with complete airway obstruction due to a foreign body.² Remove the foreign body if it is visible and the patient has become unconscious. **Use caution to prevent forcing the object further into the airway.** Instrument removal of airway foreign bodies with an airway forceps is possible if the foreign body is visible and within reach of the forceps (Chapter 207).

The options for positive-pressure ventilation include mouth-to-mouth, mouth-to-mask, and bag-valve devices (i.e., mask ventilation) once the airway is patent. The remainder of this section will review the latter, as the other two options are not used in Emergency Departments or hospitals.

The key to effective mask ventilation is ensuring a continually patent airway. This is initially achieved by placing the patient in the sniffing position coupled with a combination of chin-lift and jaw-thrust. Neglect of this key maneuver leads to excessive use of positive-pressure ventilation in an attempt to compensate for an obstructed upper airway. Improper patient positioning associated with positive-pressure ventilation will force gas into the stomach, increase intraabdominal pressure, and result in the need for ever-increasing positive pressure on the airway. Rising intraabdominal pressure will eventually make ventilation difficult, impossible, or significantly increase the risk of gastric aspiration. **Always keep in mind the importance of proper positioning and the use of an appropriately sized oral or nasal airway as an adjunct.**

Face masks are made of clear plastic and/or silicone, have a soft seal, and have an anatomic shape that conforms to the contours of the patient's face (Figures 10-10, 10-11, and 10-12). They are compatible with bag-valve devices, leak-proof, and lightweight; often include a color-coded ring; are single use; and are transparent to observe the patient. A soft inflatable cushion seals to the contours of the patient's face. Typical adult sizes are 3, 4, and 5. **The mask must be large enough to completely cover the nose, mouth, and chin but not so large as to allow a leak.** This allows effective ventilation through the mouth and nose. **It should not cover any part of the patient's eyes.**

There are ergonomically designed face masks in a variety of sizes. The ErgoMask (Touren Medical, Beijing, China) is one example (Figure 10-11). It is designed asymmetrically with the ventilation port being off-center. It was meant for efficient ventilation. The ErgoMask has contoured ridges and a colored marker for grip

FIGURE 10-9. The Dual-Air Adjustable Oropharyngeal Airway. (Courtesy of NuZone Medical, Spokane, WA.)

FIGURE 10-10. Examples of face masks. **A.** Standard face masks with color-coded size rings. **B.** Standard face masks without color-coded size rings.

placement. The Premium ERGO Mask (SunMed, Grand Rapids, MI) is another example (**Figure 10-12**). It was designed with an ergonomic shape and finger grips to allow a secure grip. It is color-coded for size selection and available in six sizes.

There are two ways to properly hold a face mask. The one-handed technique is performed with the nondominant hand holding the mask (**Figure 10-13**). Stand at the top of the bed looking down at the patient's head. Place the little, ring, and middle fingers under the patient's mandible. Place the index finger and thumb on the bottom and top portions of the mask. **This technique allows the simultaneous jaw-thrust of the mandible and extension of the atlanto-occipital joint while applying enough downward pressure on the face mask to create an airtight seal.** An elastic head strap is a very helpful device to aid in sealing the mask tightly. The dominant hand is used to ventilate the patient through the bag-valve device.

The face mask may sometimes not form a good seal against the face. This results in poor ventilation and increased pressure to move

air. Adjust the air in the cushion, apply water-soluble lubricant to the cushion, or apply a clear dressing (e.g., Tegaderm) to the patient's face.²³⁻²⁵ These techniques overcome a poor seal.

A two-handed technique may be necessary in patients with facial hair and those who are edentulous, elderly, or obese.^{26,27} The two-handed technique is more effective.^{27,28} Two people are required to perform this technique. The Emergency Physician applies both hands to the face mask to aid in the creation of a tight seal and align the airway properly (**Figure 10-14**). Place the face mask on the patient's face. Place the index, middle, ring, and small fingers of the left hand on the body of the left side of the patient's mandible. Position the right hand similarly on the right side of the patient's mandible. Apply both thumbs to the mask and apply pressure to create a seal (**Figure 10-14**). Anteriorly elevate the mandible to perform the jaw-thrust maneuver. The two-person technique and makes it necessary to have an assistant apply positive pressure through the bag-valve device attached to the face

FIGURE 10-11. The ErgoMask. **A.** The mask. **B.** Holding the mask. (Courtesy of Tauren Medical, Beijing, China.)

FIGURE 10-12. The Premium ERGO Mask. (Courtesy of SunMed, Grand Rapids, MI.)

mask. It is preferable, when possible, to use the two-person technique because this method results in improved bag-valve-mask ventilation.²⁹

A face mask can present difficulties in its use.^{30,31} Difficult patient indicators include edentulousness, facial hair, male sex, Mallampati class III and IV, neck irradiation, obesity, obstructive sleep apnea, older age, and snoring. Make sure the face mask fits properly. Consider using a two-handed technique if the one-handed technique is unsuccessful.

THE NUMASK

A device can be used to assist in ventilation instead of a traditional face mask. The NuMask (NuMask Inc., Woodland Hills, CA) solves the problem of having to create an airtight face mask seal.^{32,33} This device is an intraoral mask for teenagers and adults

FIGURE 10-13. The one-handed, one-person mask ventilation technique.

FIGURE 10-14. The two-handed, two-person mask ventilation technique.

that connects to a bag-valve device and eliminates the need for a face mask (**Figure 10-15A**). It is translucent to visualize the oral contents and the patient. There is an indentation at the bottom and top that allows insertion in any direction and to protect the frenulum from damage. It is especially useful in patients in whom it is difficult to get a good face mask seal (e.g., obese, facial hair, facial trauma) or in the one-person bagging technique. The company makes a retention shield that wraps around the patient's head to secure the device and seal the patient's nostrils. This allows for easy one-person bagging.

The NuMask is simple to insert into the patient's mouth. Place the device into the patient's mouth. Ensure the soft wings sit between the patient's teeth/gums and the cheeks/lips (**Figure 10-15B**). Use the thumb and index finger of the nondominant hand to pinch the patient's nostrils closed (**Figures 10-15C and D**). Use the hand and remaining fingers to wrap around the external tube portion and to seal the patient's lips over the intraoral portion of the device (**Figures 10-15C and D**). The moisture in the patient's oral cavity maintains the airtight seal. Attach the bag-valve device and begin ventilations. Remove the NuMask, insert an oral airway, replace the NuMask, and begin ventilations if ventilation is difficult.

There are numerous advantages to using the NuMask over the traditional face mask.³²⁻³⁴ It is ideal for operators with small hands who have difficulty grasping and maintaining a seal with a face mask. It is easier to maintain a seal than a face mask. Ventilation is easier when only one person is available to bag and ventilate the patient. It can be used in patients in whom a good face mask seal is difficult. The device can be used in conscious and unconscious patients as it does not cause a gag reflex. The one size available will fit most teenagers and adults. A pediatric version is not available. It can be used with an oral airway (**Figure 10-15E**).

THE BAG-VALVE DEVICE

A bag-valve device is used to provide positive-pressure ventilation. It consists of a self-inflating bag connected to oxygen on one end and a one-way nonbreathing valve on the other. They are available in several sizes depending on the age of the patient (**Figure 10-16**). The valve end is connected to the face mask or other airway device to allow one-way flow of oxygen. The other end has tubing to attach the bag to an oxygen source. This device can also force air into the esophagus and stomach and place the patient at risk for aspiration if not used properly.

FIGURE 10-15. The NuMASK intraoral mask. **A.** The device. **B.** The device is inserted between the patient's teeth/gums and their lips/cheeks. **C.** Proper hand positioning to seal the patient's nostrils and lips. **D.** An alternative hand positioning. **E.** Use with an oral airway. (Parts A and E courtesy of NuMask Inc., Woodland Hills, CA.)

It may be difficult to provide adequate ventilatory volumes through the bag-valve device attached to a face mask. This is often due to an inadequate seal of the face mask on the patient while maintaining an open airway. It can result from inadequate squeezing

of the bag to generate an appropriate volume of air flow. Consider using the two-person technique to resolve these issues. Change the face mask from the standard teardrop-shaped mask to a circular-shaped face mask if ventilation is difficult in a child.

FIGURE 10-16. The bag-valve-mask device. From top to bottom: adult size, child size, and infant size.

Stand above the patient's head. Place the patient in the sniffing position. Apply a face mask. Attach the bag-valve device to the face mask and begin positive-pressure ventilation. Begin ventilations at a rate of 10 to 12 per minute or squeeze the bag every 5 to 6 seconds. Apply the jaw-thrust and/or chin-lift maneuvers if ventilation is difficult. Insert an oral or nasal airway if ventilation is still difficult. The patient requires an invasive airway device immediately if ventilation is still difficult.

The LiteSaver (Mercury Medical, Clearwater, FL) overcomes many problems associated with bag ventilation (**Figure 10-17**). The built-in red light is activated by pulling a tab. It blinks every 6 seconds or 10 times a minute to administer a breath and prevent

FIGURE 10-17. The LiteSaver bag-valve device. **A.** Ready to use. **B.** The tab pulled and the light blinking red when the device is activated. (Courtesy of Mercury Medical, Clearwater, FL.)

hyperventilation and hypoventilation. Breaths at the blinking light allow sufficient expiration to avoid breath stacking. The manometer can show how much pressure is being applied with each breath. Pressures lower than 20 to 25 cmH₂O decrease aspiration. Having the manometer and timing light built in to the bag eliminates the need for additional equipment.

The American Society of Anesthesiologists has published an algorithm to facilitate decision making in the face of airway management problems. A detailed discussion of the various intubation options is contained in later chapters.

IMPEDANCE THRESHOLD DEVICES

The ResQGARD and ResQPOD (Advanced Circulatory Systems Inc., Roseville, MN) were designed as adjuncts to ventilation (**Figure 10-18**).^{35,36} They increase diastolic and systolic blood pressures while improving cerebral blood flow. Both devices can be used with endotracheal tubes, airway devices, or a standard face mask.

The ResQGARD is a noninvasive device to improve blood pressure in hypotensive patients (e.g., blood loss, dehydration, overdose, and sepsis). It is used in spontaneously breathing patients and attaches to the face mask. It creates a resistance when the patient inhales to enhance the vacuum in the chest. The vacuum draws blood back to the heart, increases preload, improves cardiac output, and lowers intracranial pressure. It results in improved organ blood flow in addition to the increased blood pressure.

The ResQPOD is used during cardiopulmonary resuscitation. It impedes airflow into the lungs until the threshold of -10 cmH₂O is reached but not out of the lungs during exhalation. It increases the negative intrathoracic pressure to enhance circulation. The integrated timing light flashes at a rate of 10 times per minute to as a reminder to administer ventilations only with the lights.

PEDIATRIC CONSIDERATIONS

Significant differences exist between the adult and pediatric airway (Chapter 9 and **Table 10-2**).³⁷ The ratio of head to body size is greater in infants and young children. Care must be taken to achieve proper positioning for optimal airway angulation. A towel may be placed under an infant's shoulders, while younger children may be optimally positioned while lying flat on the stretcher. Older children may require a towel under the head to achieve ideal positioning.^{37,38} Loss of tone in the muscles supporting and protecting the upper airway may still result in an airway obstruction despite proper head positioning. This may be corrected by the use of a chin-lift, jaw-thrust, nasal airway, or oral airway.

Infants and children have a higher minute ventilation and cardiac output than adults and higher basal oxygen consumption. Infants and children have a lower functional residual capacity, which leads to oxygen desaturation more rapidly than in adults when apnea occurs. Hypoxic bradycardia can be prevented or reversed when oxygenation and ventilation are provided in an effective and efficient fashion.³⁸

Properly sized equipment remains crucial to the success of airway management and can be addressed by the use of the Broselow tape. It should be noted that there is insufficient evidence for or against the routine use of supraglottic or extraglottic airway devices during pediatric cardiac arrest. A meta-analysis of in-hospital use of laryngeal mask airways cited aspiration as an infrequent complication in pediatric patients. Their use is an acceptable adjunct in the hands of experienced providers but is associated with a higher incidence of other complications in young children (e.g., failed insertion, need for repositioning, and poor seals).³⁹ Nasal airways are

FIGURE 10-18. Impedance threshold devices. **A.** The ResQGARD. **B.** The ResQPOD. (Courtesy of Advanced Circulatory Systems Inc., Roseville, MN.)

underused in pediatric patients. Oral airways are often not helpful but do not harm the patient if the right size is used properly.

COMPLICATIONS

The most serious complication of basic airway management is aspiration of gastric contents. Positive pressure can force air into the stomach and result in gastric distension. This can cause regurgitation and aspiration. The aspiration of acidic gastric contents can result in an acute chemical pneumonitis. This phenomenon is known as the Mendelson syndrome and has an associated 50% mortality.⁴⁰ It is a particularly significant risk when airway management is needed emergently or routinely in the diabetic, obese, pregnant, or trauma patient. Incorrectly sized oral airways can force the tongue back and cause an airway obstruction.

Less serious complications include soft tissue trauma to the eyelids, lips, oral cavity, and tongue. Tooth fractures or avulsions are uncommon but possible injuries. A dermatitis or allergic reaction to the plastic material is rarely seen. Facial nerve dysfunction

due to pressure effects of the mask are transient. Corneal abrasions, conjunctival chemosis, and increased intraocular pressure are common with masks that are too large. Epistaxis can result from a nasal airway.⁴¹ Incorrect insertion of a nasal airway can damage the turbinates.⁴¹ This is troublesome and can sometimes result in blood aspiration. Lifting of the mandible in difficult face mask ventilation can result in bruising, pain, and mandibular dislocations.

Traumatic injuries can result in complications from using a face mask. Pharyngeal mucosal injuries can cause subcutaneous emphysema. Patients with basilar skull fractures can experience a pneumocephalus with the use of positive-pressure ventilation.

SUMMARY

Basic airway management is a fundamental skill that must be mastered by all Emergency Physicians. It is usually possible to prevent hypoxia and hypercarbia in the apneic patient with an oxygen source, a means to deliver positive-pressure ventilation, attention to detail in positioning, and airway adjuncts. The ultimate measure of the efficacy of oxygenation and ventilation is a normal PaCO₂ and PaO₂. The various methods of securing the airway are discussed elsewhere in this text.

Noninvasive Airway Management

Gennadiy Voronov, Tamer Elattary, and Ned Nasr

INTRODUCTION

The term noninvasive ventilation (NIV) refers to delivering positive-pressure ventilation through an interface (i.e., face mask, nasal mask, or nasal plugs) rather than intubating the trachea.^{1,2} It may be used to prevent acute respiratory failure (ARF) as a prophylactic treatment, to treat ARF, or as a curative treatment to avoid reintubation.^{3,4} There are different types or modes of NIV. The most frequently used are continuous positive airway pressure (CPAP) and bilevel positive airway pressure (BIPAP). CPAP is a method to deliver constant positive airway pressure during the inspiratory and expiratory phase of breathing.⁵ BIPAP refers to the association of two positive airway pressures (i.e., pressure support ventilation [PSV] during inspiration and lesser pressure value during expiration).⁵ The pressure applied during expiration is commonly incorrectly referred to as positive end expiratory pressure (PEEP). The correct term is expiratory positive airway pressure (EPAP), or the pressure delivered throughout the expiratory phase.

Some Emergency Physicians consider high-flow nasal cannula (HFNC) as a method to deliver NIV. NIV should be well known to all Emergency Physicians caring for patients with acute respiratory failure.⁶ It is used in the Emergency Department for NIV and preoxygenation prior to intubation.⁷⁻¹² It is used as NIV by some prehospital providers.¹³⁻¹⁷ This chapter discusses CPAP and BIPAP in detail with some reference to HFNC. Other methods to deliver oxygen therapy are discussed briefly at the end of this chapter.

ANATOMY AND PATHOPHYSIOLOGY

CPAP works mainly by increasing intrathoracic pressure. It prevents airway and alveolar collapse. CPAP leads to decreased atelectasis and maintaining functional residual capacity (FRC). CPAP reduces left ventricular afterload, which may lead to an increase in cardiac output. CPAP helps to decrease the work of breathing in chronic obstructive airway disease by decreasing the inspiratory threshold load caused by intrinsic PEEP.⁵ CPAP may improve gas exchange by improving the ventilation-perfusion ratio and by increasing intraalveolar oxygen partial pressure. The tidal volume is dependent on respiratory muscles without unloading of inspiratory muscles.⁶ The increase in intrathoracic pressure can result in decreased venous return to the heart, decreasing left-sided output, and decreased blood pressure.¹⁸

The PSV portion of BIPAP is triggered by the patient's inspiratory effort. This trigger will induce positive-pressure support that helps to unload the inspiratory muscles and decrease work of breathing. Tidal volume depends on inspiratory muscle effort, respiratory compliance, and pressure support provided by the ventilator. PEEP

FIGURE 11-1. An example of the high-flow nasal cannula (HFNC).

works during expiration by the same mechanisms that CPAP works and achieves the same goals.¹⁹ BIPAP provides pump function in addition to improving gas exchange.

HFNC is used to provide oxygen therapy (**Figure 11-1**).²⁰⁻²⁴ It has humidification built into the circuit and oxygen flow of 10 to 60 L/min. HFNC looks like a regular nasal cannula with bigger prongs. It provides a small positive pressure. HFNC helps to reduce the dead space by increasing the FIO_2 and displacing CO_2 at the upper airway segments.²⁵ The HFNC decreases heat loss, decreases moisture loss, provides PEEP, and improves oxygenation.²⁵ The patient controls the CPAP and PEEP by opening their mouth. HFNC allows the patient to eat, suction, and talk. It is often used in procedural sedation and as a bridge to preoxygenate prior to intubation.

INDICATIONS

NIV was considered unsafe in the past. Many Emergency Physicians thought it was more prudent to intubate the patient than use NIV.^{4,26} This includes infants and children.²⁷ Emergency Physicians have been using NIV successfully for multiple indications over the past 20 years. The widening indications of NIV have led to improvement and advancement of ventilation techniques and equipment.

NIV is used as a prophylaxis or a curative treatment for ARF. NIV led to a decreased need for intubation in patients with chronic obstructive pulmonary disease (COPD).^{28,29} NIV also decreases mortality in patients with COPD.^{28,29} Use NIV as the first line of ventilatory support for patients with severe COPD exacerbation based on clinical practice guidelines.^{30,31} NIV significantly decreased intubation rates and mortality in cardiogenic pulmonary edema. CPAP and BIPAP are equal effective treatment for these patients.³⁰ NIV reduces left ventricular transmural pressure and increases cardiac output. NIV has been used successfully in some cases of hypoxemic respiratory failure for reasons other than cardiogenic pulmonary edema.^{32,33} However, some studies showed increases in intubation rates and hospital mortality rates.³⁴ A reason for this conflicting data may be related to the underlying cause of hypoxemic respiratory failure.

Use of NIV was beneficial in patients with hypoxemic respiratory failure resulting from pneumonia and respiratory failure after abdominal surgery.^{33,35} However, it failed to show additional benefit in cases of acute respiratory distress syndrome (ARDS).³⁶

Several studies have been conducted to investigate the benefit of NIV in severe asthmatic exacerbations.³⁷⁻³⁹ These studies showed that NIV added to conventional therapy led to decreases in intubation rates, decreases in the mean bronchodilator therapy dose, and

reductions in the need for hospitalization. However, the number of patients enrolled in these studies was small, and the recommendations concerning use of NIV in severe asthma remain controversial.⁴⁰

NIV used in patients with obesity hypoventilation syndrome admitted with acute respiratory failure was as effective as NIV in COPD exacerbations.⁴¹ NIV has been used in outpatient settings for the treatment of obstructive sleep apnea (OSA) and obesity hypoventilation syndrome.

CONTRAINDICATIONS

NIV is contraindicated in agitated patients; patients with cardiac arrest, copious secretions, facial surgery, facial trauma, the inability to protect the airway, multiple organ failure, severe hematemesis, or severe hemoptysis; patients who refuse NIV or are uncooperative; and patients who are vomiting. Apnea or respiratory arrest is an absolute contraindication for NIV because the patient should completely control the respiration in CPAP or trigger the ventilator in BIPAP. Avoid NIV in patients at high risk of aspiration or who are not able to protect the airway. Other contraindications include an elevated PCO_2 , hemodynamic instability, hypotension, and lack of trained staff.

Significantly altered mental status is considered an absolute contraindication except in patients with hypercapnic encephalopathy.⁴² Closely monitor patients with impaired consciousness due to hypercapnia being treated with NIV and intubate if further deterioration or no improvement is noted.

Avoid NIV in respiratory acidosis, severe hypoxemia, and shock because most patients will fail NIV. The observed mortality was higher than the predicted mortality scores.³⁶

Recent esophageal suturing or anastomosis surgery is a relative contraindication because high positive pressure may lead to suture disruption and leakage.⁴³ It is preferable to use CPAP over BIPAP in these cases or to use low insufflation pressure below 6 to 8 cmH_2O for PSV.³

EQUIPMENT

- Interface (see below)
- Ventilator
- Pulse oximeter
- Capnogram monitor
- Cardiac monitor
- Noninvasive blood pressure monitor
- Face masks, various sizes
- Bag-valve device
- Endotracheal tubes, various sizes
- Oxygen source, tubing, and regulator
- Advanced life support (ALS) medications
- Advanced airway equipment
- Surgical airway equipment
- Suction system

The interface is the main difference that distinguishes NIV from invasive ventilation. Available interfaces include oronasal masks, nasal masks, nasal pillows, mouth pieces, hybrid oral interface–nasal pillows, total face masks, and helmets (**Figure 11-2**).

Choosing the interface is an important step. Make every effort to try different types and sizes of interfaces to achieve optimal therapeutic results with the smallest leak possible. No difference was found between different types of interfaces in regard to minute

FIGURE 11-2. Commonly used CPAP interfaces. **A.** Oronasal mask. **B.** Nasal mask. **C.** Nasal pillow. **D.** Hybrid oral interface—nasal pillow. **E.** Total face mask. **F.** The Boussignac CPAP System.

ventilation, PCO_2 , and work of breathing.⁴⁴ The ideal interface will be the one with the lowest leakage and that provides an adequate seal with minimal pressure on the face, is well tolerated by the patient, and is easy to secure and easy to remove. The interfaces are transparent to aid in identifying any regurgitation or vomiting. Most commercially available interfaces have anti-asphyxia valves that prevent asphyxiation should any ventilator malfunction occur. Use a swivel adaptor if the patient has an orogastric or nasogastric tube (**Figure 11-3**) or special endoscopy mask to minimize the leak. Start with an oronasal mask in the Emergency Department. Have different types of interfaces immediately available for use if the patient does not tolerate the oronasal mask.

Ventilators are being used in the Emergency Department to provide NIV. The different NIV modes were added to the new-generation ventilators. Older generation ventilators were only able to provide invasive ventilation modes. Ventilators detect and compensate for any leakage. Ventilators can be adjusted to provide different oxygen concentrations (i.e., FIO_2) up to 100% oxygen. An alarm system helps to detect asynchrony and leakage. Different types of portable ventilators are used to provide CPAP for OSA.

Commonly used ventilator modes include CPAP and BIPAP. Proportional assist ventilation (PAV) and neurally adjusted ventilatory assist (NAVA) are new modes created to improve patient-ventilator synchrony.⁴⁵

CPAP can be delivered by the Boussignac CPAP System (Vygon; **Figure 11-2F**). This does not require a special ventilator. The Boussignac CPAP System uses a high-flow gas source (e.g., 30 L/min O_2 flowmeter) to create a virtual valve through turbulent flow. The

Emergency Physician can build up CPAP into the system by adjusting the flow. The advantage of this method is having an effective, lightweight, and economic system.⁴⁶

FIGURE 11-3. A swivel adaptor can be used to fit a nasogastric tube for a patient on CPAP.

PATIENT PREPARATION

The decision to use NIV implies the patient does not need emergent intubation. Most patients will need urgent management. Use the available time wisely and efficiently. **Delaying the initiation of NIV may lead to deterioration and increase the possibility of failure.**⁴⁷ Perform a quick history and physical examination to detect whether the patient will benefit from using NIV and to exclude any contraindications. Inquire about the NPO (nothing by mouth) status. **Assess the airway to predict a possible difficult intubation.** Apply cardiac monitoring, noninvasive blood pressure cuff, and pulse oximetry. Obtain and secure a well-functioning intravenous catheter.

NIV requires the full cooperation from the patient with the exception of hypercapnic encephalopathy. Thoroughly explain the process and expectations to help the patient better tolerate the mask and positive airway pressure. Obtain consent from the patient for NIV and possible invasive ventilation in case of NIV failure. Clarify advanced directives. Place the patient seated in a 30° to 90° position guided by the patient comfort. Leave any dentures in place to help with fitting the interface.

TECHNIQUE

Apply supplemental oxygen (e.g., through a nasal cannula, face mask, or nonrebreather mask) until replaced by the NIV interface. Set the ventilator to the correct settings and be ready to connect to the interface. Select the mode and adjust the initial settings (Table 11-1). Start with low pressure to help the patient tolerate and synchronize with the ventilator. Consider starting with CPAP/PEEP of 3 to 5 mmHg and PSV of 3 to 5 mmHg if using BIPAP. Start with an FIO₂ of 50% to 60%. Adjust the FIO₂ after connecting the ventilator to keep the saturation within an acceptable range. This will vary between patients depending on their baseline. A value of > 92% is commonly used. Start with initial trigger of -1 to -2 L/min or -1 to -2 cmH₂O, and adjust it to reach the lowest level that prevents auto-triggering.

Ensure the patient is positioned properly. Remove the supplemental oxygen device and replace it with the NIV interface. The patient may know which interface fits the best. Apply the interface without connecting the ventilator. Avoid excessive pressure or strap tension on the patient. Encourage the patient to hold the interface while applying it and to take a few breathes before connecting the ventilator. Connect the ventilator and allow the patient to synchronize with the ventilator. Gradually increase the pressure settings

TABLE 11-1 Initial Ventilator Settings for NIV

Ventilator mode Assist control (AC)	Respiratory rate 8–14 breaths/min
Breath type Pressure	Beware of settings too high Patient must be breathing on their own
IPAP 12–20 cmH ₂ O Titrate to respiratory rate Titrate to work of breathing Titrate 2 cmH ₂ O every 5 minutes	Inspiratory time Adjust to patient
EPAP 6–12 cmH ₂ O Start with 6–8 cmH ₂ O for asthma Start with 6–8 cmH ₂ O for chronic obstructive pulmonary disease Start with used CPAP for obstructive sleep apnea Start with 10–12 cmH ₂ O for pulmonary edema Titrate 2 cmH ₂ O every 5 minutes	Oxygen concentration FIO ₂ room air to 100% Adjust to pulse oximetry > 92%

(i.e., CPAP/PEEP and PSV) as tolerated by the patient to achieve an adequate tidal volume of 6 to 10 mL/kg with good synchronization and without major leak. **Never exceed a total pressure (i.e., PSV + PEEP) of 25 cmH₂O because this may lead to gastric insufflation.** It is best to connect a nasogastric tube, if the patient has one in place, to a bag rather than suction to detect gastric insufflation.

The success of NIV depends mainly on improving synchronization and minimizing the leak. Frequently check the device. Keep reassuring the patient. Continue to adjust the interface position and pressure setting as required. Monitor the patient for the need for orotracheal intubation.

ASSESSMENT

NIV requires close monitoring and assessment of the patient. Continuous cardiac monitoring and pulse oximetry are mandatory to assess proper oxygenation. Use capnography to assess ventilation. Obtain an arterial blood gas (ABG) within 1 to 2 hours of NIV initiation to assess the patient's response. Improvement of pH, PO₂, and/or PCO₂ can be used as a sign to predict NIV success.⁴⁸ **The early identification of asynchrony is crucial since proper management will decrease failure of NIV.** Asynchrony can be related to the underlying disease or the presence of a leak.⁴⁹

Steps can be taken to minimize the leak. This includes adjusting the interface position, switching between different interfaces, adjusting the ventilator settings, and gradually increasing the pressure support from the initial settings. Some ventilators provide a leakage compensation feature. PAV mode was used to improve patient tolerance and synchrony with the ventilator. It is not superior to intubation rates or overall mortality.^{50,51}

One of the most important points in management of NIV is rapid recognition of failure.⁵² The reported failure rate varies from 5% up to 40%.⁵³ It is difficult to predict which patients will fail NIV. Failure risk factors may encourage the Emergency Physician to closely monitor the patient to identify failure early (Table 11-2).^{54,55} A patient is considered to have failed NIV if the ABG revealed worsening of the pH, PO₂, and/or PCO₂. **Terminate the NIV if the patient is exhibiting worsening of hemodynamics, worsening of agitation, or worsening of consciousness or is unable to clear secretions, unable to protect their airway, or unable to tolerate NIV despite all steps to help with synchronization, and perform immediate intubation.**⁴⁸

AFTERCARE

Take every possible step to prevent pressure ulcers from excessive pressure by the interface. Multiple studies suggest that applying humidification may improve patient comfort and increase

TABLE 11-2 The Risk Factors for Failure of NIV

Age > 40 years	Initial high CO ₂
Agitation	Initial high FIO ₂ requirement
Air leak	Low patient PO ₂ /FIO ₂
Asynchrony with ventilator	No improvement after 2 hours of NIV
Decreased consciousness (e.g., Glasgow coma scale score < 11)	pH < 7.25
Diagnosis of acute respiratory distress syndrome (ARDS)	Respiratory distress
Edentulous	Severe tachycardia
Elevating CO ₂	Severe tachypnea > 35 breaths/min
Elevating FIO ₂ requirements	Underlying ARDS
Excessive secretions	Underlying immunocompromise
Failure to wean FIO ₂	Underlying oncologic problem
Hemodynamic instability	Underlying sepsis
	Ventilator intolerance

tolerance by decreasing dryness of the upper airway.⁵⁶ This is controversial.

The use of sedation during NIV is poorly studied. Some Emergency Physicians advocate administering sedation to improve patient tolerance and NIV success. Others are concerned that sedation may worsen the level of consciousness or depress respiration. Various agents have been used for sedation during NIV (e.g., benzodiazepines, dexmedetomidine, ketamine, and opioids).⁵⁷⁻⁵⁹ Dexmedetomidine has the advantage of having a minimal effect on the respiratory center. Combination therapy with several sedatives may have deleterious effects and may lead to NIV failure.⁶⁰ **The decision to use sedation must be individualized for each patient. Use a single agent and titrate it cautiously with close monitoring of the level of consciousness and respiratory parameters.**

Where and when to admit the patient is a very important question once NIV is initiated. NIV is typically initiated in the Emergency Department followed by transfer of the patient to an intensive care unit or step-down unit. It is crucial to have the proper monitors and trained personnel available 24 hours a day.⁶¹ Admit and transfer the patient after the initial assessment of NIV success and stabilization of the patient's condition. Transfer the patient with NIV applied and with monitors. NIV is usually applied in 60- to 90-minute durations at 2- to 3-hour intervals. Weaning is performed by increasing the disconnection time, decreasing the ventilator positive pressure parameters, or a combination of both.

COMPLICATIONS

NIV is generally safe, and serious complications are rare. Minor complications include interface discomfort or a minor leak. This can be resolved by adjusting the interface, minimizing the strap tension while maintaining a minimal leak, or switching interfaces. Dryness of the upper airway can cause discomfort. Dryness is managed by adding humidification. Other minor complications include eye dryness and minor gastric distention.

Serious complications may have a detrimental effect on the patient. Nasal bridge skin ulceration is a result of excessive pressure while trying to minimize leaks. Steps to prevent this include decreasing the strap tension, using masks with soft cushions on the nose, and using the interface provided with a forehead cushion. Switching masks (e.g., nasal pillows or total face mask) will minimize the possibility of nasal ulceration. The application of artificial skin (e.g., Duoderm) is an additional step taken by some Emergency Physicians to protect against nasal ulceration. Increased intrathoracic pressure can result in hypotension, hemodynamic compromise, and deterioration. Attempt to lower the pressure to resolve this.

Gastric distention results from excessive pressure support. It may lead to vomiting or regurgitation. **The total pressure support (i.e., PSV + PEEP) should not exceed 25 cmH₂O.** Connect any nasogastric tube to a bag to recognize gastric distention.

The inability to recognize NIV therapy failure may delay necessary intubation and lead to increased morbidity and mortality.⁶² Guard against delays in intubation by identifying patients who would benefit from NIV, excluding the patients with contraindications to NIV, and closely monitoring to identify the early signs of NIV failure.

OTHER NONINVASIVE DEVICES TO DELIVER OXYGEN

A wide variety of devices are being used to provide supplemental oxygen (i.e., FIO₂ > 21%). They can be used as a primary oxygen treatment or as a transient bridging measure until more advanced airway management is prepared.

FIGURE 11-4. An example of the nasal cannula.

NASAL CANNULA

The nasal cannula is one of the most widely used devices to deliver supplemental oxygen (Figure 11-4). Adjust the oxygen flow between 1 and 6 L/min. There is an increase of 4% in FIO₂ for each L/min of oxygen flow. The delivered FIO₂ ranges from 25% for 1 L/min to 45% for 6 L/min. Further increases in the oxygen flow will have no additional effect on FIO₂. The FIO₂ delivered by nasal cannula is affected by the minute ventilation so that an increase in minute ventilation will result in a decrease in the FIO₂. Nasal dryness may ensue and lead to patient discomfort if the flow increases beyond 4 L/min. This can be alleviated by adding humidification to the oxygen.

SIMPLE FACE MASK

The face mask is another frequently used device to deliver oxygen (Figure 11-5). The FIO₂ will increase by 4% for each L/min of oxygen flow, similar to a nasal cannula. The minimum oxygen flow should be 5 L/min to prevent rebreathing of exhaled CO₂. Adjust the oxygen flow to between 5 and 10 L/min. The FIO₂ delivered by a simple oxygen mask ranges from 40% to 60%. The increase in minute ventilation will decrease the delivered FIO₂. A face mask is less likely to cause nasal mucosa dryness compared to a nasal cannula.

VENTURI MASK (AIR-ENTRAINMENT MASK)

This device depends on the Venturi effect to entrain air that mixes with oxygen to deliver a fixed FIO₂ (Figure 11-6). The Venturi effect occurs when a fluid or gas flows through a narrowing, leading to an increased velocity and creation of negative pressure.

FIGURE 11-5. An example of the simple face mask.

FIGURE 11-6. The Venturi mask. The indicator identifies how much oxygen flow is being delivered.

FIGURE 11-7. An example of the nonrebreather face mask.

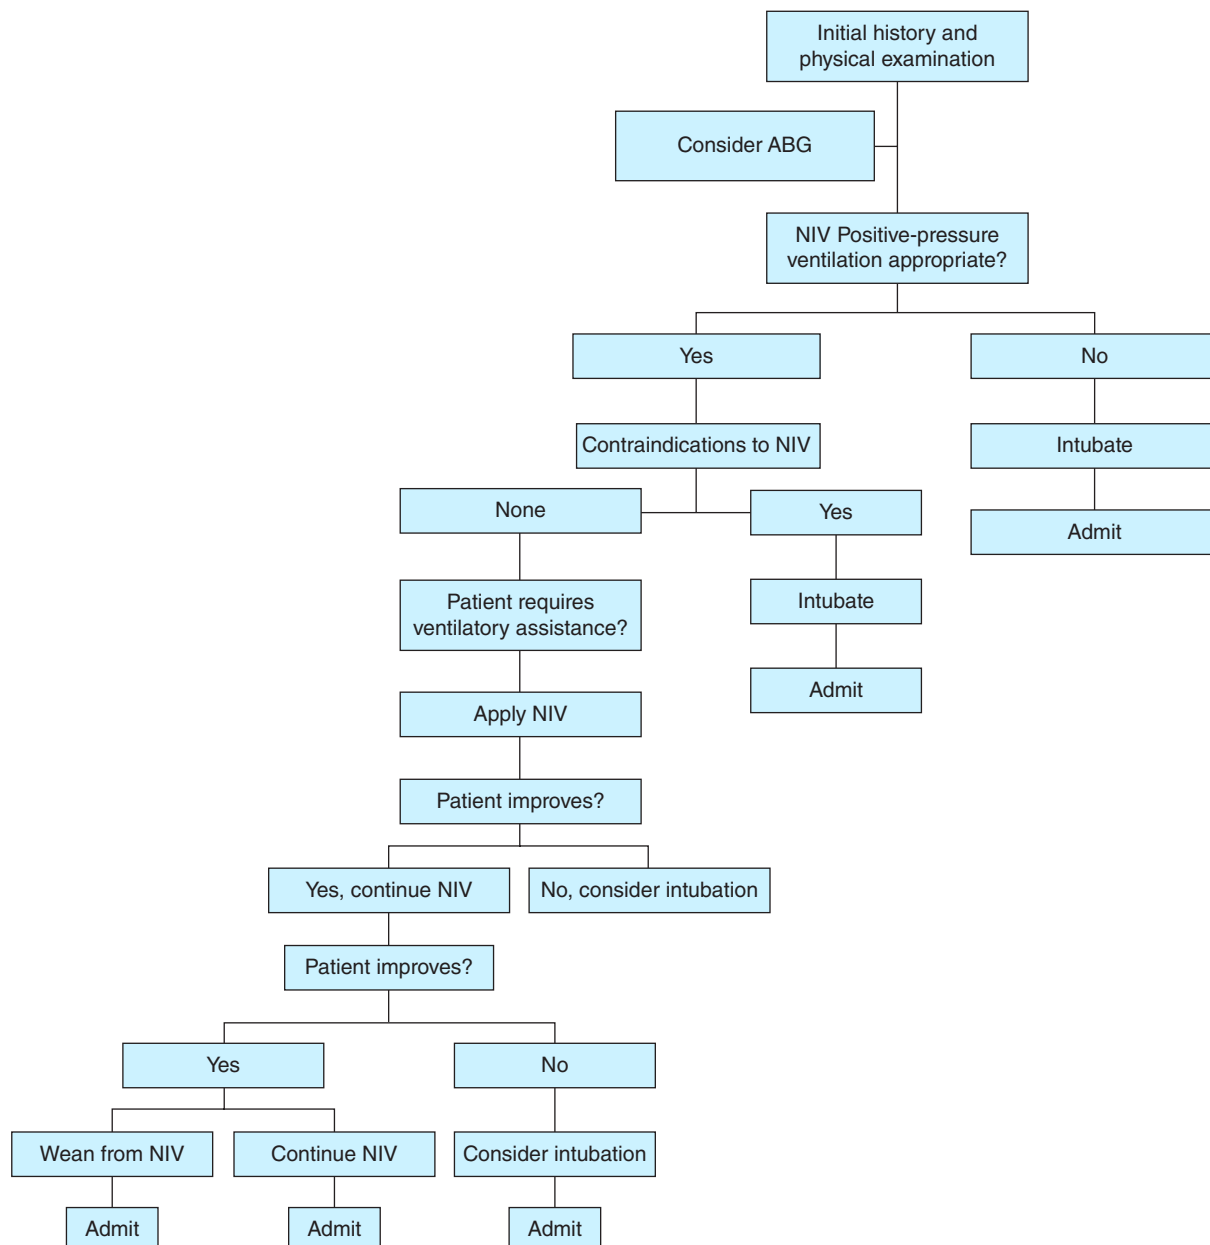

FIGURE 11-8. An algorithm for NIV. ABG, arterial blood gas;

The negative pressure will help to entrain air. The delivered FIO_2 ranges from 24% to 50%. The Venturi device will indicate how much oxygen flow is needed to deliver certain FIO_2 concentrations (**Figure 11-6**). FIO_2 delivered by a Venturi mask is not affected by minute ventilation and is usually used when a precise FIO_2 is desired.

NONREBREATHING FACE MASK

A nonrebreather mask is a face mask that contains a 1-L reservoir bag (**Figure 11-7**). There are two valves in a nonrebreather mask. One prevents entrainment of room air. The other prevents mixing the oxygen in the reservoir bag with exhaled air. Adjust the oxygen flow to between 8 and 15 L/min to ensure filling of the reservoir bag and prevent the bag from collapsing during inspiration. The delivered FIO_2 can range from 60% to 90%.

PARTIAL REBREATHING FACE MASK

The design of a partial rebreathing mask is similar to the nonrebreathing mask except it lacks the valve between the mask and the reservoir bag. The first portion of the exhaled air (i.e., 150 mL that represents the dead space) enters the reservoir bag. The dead space contains very little CO_2 . The delivered FIO_2 can reach up to 80%. Oxygen flow ranges between 8 and 15 L/min with a target to prevent the reservoir bag from collapsing during inspiration.

SUMMARY

NIV is an effective management that has been used in a wide variety of acute clinical conditions to treat or prevent acute respiratory failure (**Figure 11-8**). It is used in the resuscitation of the critically ill patient. The benefit of avoiding endotracheal intubation encouraged many Emergency Physicians to try NIV as a first line of ventilatory support. Be familiar with the contraindications to using NIV. Monitor the signs of NIV failure. Delaying intubation when it is indicated may lead to increased morbidity and mortality. Emergency Physicians should be aware of the FIO_2 values that can be delivered by the supplemental oxygen devices. The use of NIV may prevent intubation, admission to the intensive care unit, the use of intensive care unit resources, and increased costs to the patient. Consider the use of NIV by a helmet interface in end-of-life care (**Figure 11-9**).

Pharmacologic Adjuncts to Intubation

Ned F. Nasr, David W. Boldt, and Isam F. Nasr

INTRODUCTION

Reserve oral endotracheal intubation without pharmacologic assistance for the unresponsive and apneic patient. Intubate unconscious patients capable of resisting laryngoscopy or those with spontaneous respiratory effort with the assistance of pharmacologic adjuncts. Rapid sequence intubation (Chapter 16) optimizes conditions while minimizing the risk of aspiration. It can be performed with a high rate of success and minimal complications.¹ Rapid sequence intubation requires the use of several pharmacologic adjuncts (Tables 12-1, 12-2, and 12-3). This includes a potent anesthetic agent to induce unconsciousness and a neuromuscular blocking agent to produce paralysis.

TABLE 12-1 Recommended Anesthetic Doses of Pharmacologic Agents Used for Rapid Sequence Intubation

Medication	Adult dose (mg/kg)	Pediatric dose (mg/kg)	Onset (sec)	Duration (min)
Dexmedetomidine	0.001	0.0005–0.0010	15–45	12–20
Etomidate	0.2–0.3	0.2–0.3	15–45	3–12
Fentanyl	0.005–0.015	0.005–0.015	15–45	30–60
Ketamine	1–2	1–3	45–60	10–20
Methohexital	1–3	1–2	< 30	5–10
Midazolam	0.2–0.4	0.5–1.0	30–90	10–30
Propofol	1.5–2.5	2.5–3.5	15–45	5–10
Thiopental	2–5	2–6	< 30	5–10

TABLE 12-2 Recommended NMB Agents for Intubation and Rapid Sequence Intubation

Medication	Histamine release	Active metabolites	Adult dose (mg/kg)	Pediatric dose (mg/kg)	Time to maximum onset (min)	Duration (min)	Infusion (mcg/kg-min)	Elimination	Action
Atracurium	Yes	No	0.5	0.5	3	20–35	5–20	Hoffman, 5–10% renal	Intermediate
Pancuronium	No	Yes	0.05–0.1	0.07–0.10	2–3	40–100	0.8–1.7	40–70% renal, 15% hepatic	Long
Rocuronium	No	No	0.6	1.0	4–6	15–85	8–12	33% renal, < 75% hepatic	Intermediate
Rocuronium for RSI	No	No	0.9–1.2	1.0–1.2	1.0–1.5	30–110	N/A	33% renal, < 75% hepatic	Intermediate
Succinylcholine	No	No	0.6–1.0	1–2	1	2–3	N/A	Plasma cholinesterase	Short
Succinylcholine for RSI	No	No	1.5	2	1	3–5	N/A	Plasma cholinesterase	Short
Vecuronium	No	Yes	0.1	0.05–0.10	3	30–40	0.8–1.7	10–50% renal, 35–50% hepatic	Intermediate
Vecuronium for RSI	No	Yes	0.3–0.5	0.3–0.5	1	45–60	N/A	10–50% renal, 35–50% hepatic	Intermediate

N/A, not applicable; RSI, rapid sequence intubation.

INDUCTION AGENTS

The ideal induction agent has an extremely rapid onset of action, produces predictable deep anesthesia, has a short duration of action, and has no adverse effects.² Such an agent does not yet exist. There are at least six drugs that can safely be used for induction of anesthesia and intubation (e.g., etomidate, fentanyl, ketamine, methohexital, midazolam, propofol, and thiopental). Midazolam and fentanyl may be used alone or in conjunction with the above agents.² **The decision as to which induction agent is the most suitable is largely dependent on the Emergency Physician's experience and their understanding of each drug's properties.**

TABLE 12-3 Drug Interactions of NMB Agents

Causes NMB prolongation

Aminoglycosides
Beta-blockers
Calcium channel blockers
Clindamycin
Corticosteroids
Cyclosporine
Enflurane
Furosemide
Halothane
Isoflurane
Lithium
Local anesthetics
Magnesium
Methylxanthines
Methoxyflurane
Nitrous oxide
Potassium
Procainamide
Quinidine
Tetracycline
Vancomycin

Causes NMB resistance

Caffeine
Calcium
Carbamazepine
Phenytoin
Ranitidine
Theophylline

Each of these drugs is briefly detailed as to its pharmacokinetics, mechanism of action, pharmacodynamics, administration, and adverse effects.

BARBITURATES

Barbiturates have been a mainstay in the induction of anesthesia for more than 50 years. **Barbiturates rapidly produce sedation and hypnosis in a dose-dependent fashion.** They are less expensive than many of the newer induction agents.² The most commonly used barbiturates are thiopental (Pentothal) and methohexital (Brevital) because of their high potency, rapid onset, and short duration of action.

PHARMACOKINETICS

These ultra-short-acting barbiturates can produce effects in one arm-brain circulation time or less than 30 seconds when injected by the intravenous (IV) route.³ The onset of central nervous system (CNS) depression is primarily due to the rapid distribution of thiopental and methohexital to the well-perfused and low-volume central compartment (i.e., mainly the brain and liver). Approximately 15% of these lipid-soluble drugs remain unbound and free to diffuse across the blood-brain barrier at high initial concentrations. Brain levels peak in about 1 minute. The duration of a single dose of thiopental is approximately 5 to 10 minutes, while an equipotent dose of methohexital lasts approximately 4 to 6 minutes.⁴ The short duration of action is due to the redistribution of the drugs from the small-volume central compartment to the large-volume peripheral compartment, which is predominantly lean muscle.

Thiopental and methohexital are metabolized in the liver and excreted by the kidneys. Methohexital has a substantially higher hepatic extraction ratio, which may account for its shorter duration of action. Clearance of the drugs has little to do with the cessation of CNS effects in single or multiple small doses. The concentration in the peripheral tissue approaches the plasma concentration, and the rate of redistribution is greatly diminished if barbiturates are given in multiple high doses or in an infusion.⁵ This prolongs their anesthetic effects.⁵

MECHANISM OF ACTION

Barbiturates, along with other common IV anesthetic agents, are postulated to act on the γ -aminobutyric acid (GABA) receptor complex. These drugs work on the GABA_A receptor.⁶ **GABA is the**

principal inhibitory neurotransmitter in the CNS. The GABA receptor complex forms a transmembrane chloride channel when activated. The influx of chloride ion causes hyperpolarization and functional inhibition of the postsynaptic neurons. Barbiturates can act on the GABA receptor in two ways. Barbiturates at lower doses may potentiate the action of endogenously produced GABA by decreasing the rate of its dissociation from the receptor complex. Barbiturates at higher doses may directly activate the chloride ion channels and inhibit neuronal activity.² **It is important to note that barbiturates do not inhibit sensory impulses and therefore have no analgesic effect.** They may produce hyperalgesia (i.e., increased response to painful stimuli) when given in subhypnotic doses.²

■ PHARMACODYNAMICS

Barbiturates produce dose-dependent depression of cerebral oxygen metabolism ($CMRO_2$), cerebral blood flow (CBF), and electroencephalogram (EEG) activity. A flat EEG tracing correlates to a maximal barbiturate suppression of $CMRO_2$ to 55% of normal.² The diminished $CMRO_2$ and CBF lead to a decrease in intracranial pressure (ICP). Barbiturates lower mean arterial pressure less than they lower ICP. Cerebral perfusion pressure (CPP) is usually enhanced. Barbiturates are commonly used in neuroanesthesia and in treatment of acute brain injury.

The cardiovascular effects of barbiturates include decreased cardiac output, decreased systemic arterial pressure, and a direct negative inotropic effect on the myocardium. Barbiturates decrease cardiac output primarily by depressing the vasomotor center, cause peripheral vasodilatation, and decrease venous return to the heart. Thiopental and methohexital have a positive chronotropic effect on the heart. Methohexital produces a greater increase in heart rate, which may explain why an equipotent dose of methohexital produces significantly less hypotension than does thiopental.² Myocardial oxygen demand is increased while coronary vascular resistance is decreased, although the increase in heart rate mitigates the decrease in blood pressure. Coronary blood flow will increase to meet the increased demand if the aortic pressure remains stable. **Barbiturates must be used cautiously in any patient whose condition is sensitive to tachycardia or a decrease in preload (e.g., hypovolemia, congestive heart failure, ischemic heart disease, or pericardial tamponade).** Methohexital has less cardiovascular depressant effects and a shorter duration of action, which makes it more useful than thiopental in the Emergency Department.

Barbiturates cause dose-dependent central respiratory depression characterized by diminished tidal volume and minute ventilation. The rate and depth of respiration may be suppressed to the point of apnea. The physiologic response to hypercarbia and hypoxemia may be blunted after the hypnotic effects have dissipated. All these effects may be greatly exaggerated with the concomitant use of opioids and in patients with chronic obstructive pulmonary disease.⁷

■ ADMINISTRATION

Thiopental and methohexital are available as sodium salts and should be dissolved in 0.9% saline. The recommended dose of thiopental is 3 to 5 mg/kg in adults, 5 to 6 mg/kg in children, and 6 to 8 mg/kg in infants IV given over 1 minute. The recommended dose of methohexital is 1 to 3 mg/kg IV over 30 seconds. **Reduce the induction dose in patients premedicated with fentanyl or midazolam.** Doses may have to be adjusted in patients with known hepatic or renal disease because decreased plasma albumin levels leave a greater fraction of barbiturate available to cross the blood-brain barrier. Make a 30% to 40% reduction in the geriatric population since their diminished muscle mass slows the rate of redistribution and lengthens the duration of CNS effects.²

■ ADVERSE EFFECTS

The most significant complications of barbiturate therapy stem from their cardiopulmonary depressant effects. Use barbiturates with caution in patients who are hypovolemic, have significant cardiovascular disease, or have reactive airway disease. Thiopental can raise plasma histamine levels, which may be associated with a transient skin rash and bronchospasm. Its use should be avoided in patients with a history of hypersensitivity to barbiturates. Severe anaphylactic reactions are extremely uncommon.² Laryngeal reflexes appear to be more active with thiopental than with propofol. Avoid thiopental in people with asthma.² Laryngospasm following induction with thiopental is more likely the result of airway manipulation in a “lightly anesthetized” patient.² Methohexital has known epileptogenic effects, causes myoclonic tremors, and can cause other CNS excitatory side effects (e.g., hiccups).² Barbiturates stimulate the production of porphyrins and are contraindicated in patients with acute intermittent porphyria, variegate porphyria, and hereditary coproporphyria.² Pain at the site of IV injection is more common with the administration of methohexital than thiopental. Extravascular or intraarterial injection of these drugs may cause severe pain, tissue necrosis, and thrombosis, leading to potential nerve damage and gangrene due to their high alkalinity with a pH of 10.

Treat intraarterial injection promptly by initially diluting the barbiturate with saline injected through the catheter in the artery. Consider the administration of intraarterial heparin, lidocaine, papaverine, or phenoxybenzamine to cause vasodilation and prevent vessel thrombosis.² Sympathectomy of the involved upper extremity by a stellate ganglion or brachial plexus block can be performed by an Anesthesiologist to relieve the vasoconstriction.

An additional concern relating to the high alkalinity of these solutions is the rapid injection through the same IV line with highly acidic drugs (e.g., neuromuscular blockers), which results in precipitation. This may lead to permanent blockage of the IV line at a time when access is crucial. It is recommended to flush the IV line thoroughly following the administration of barbiturates and before the administration of the next agent.

ETOMIDATE

Etomidate (Amidate) is an ultra-short-acting hypnotic unrelated to any other IV anesthetic agent. It is highly potent and produces a rapid onset of anesthesia. It lacks the barbiturates' cardiac depressant side effects. Etomidate has become a popular induction agent and is now the induction agent of choice in many Emergency Departments for rapid sequence intubation given its favorable profile.⁸

■ PHARMACOKINETICS

Etomidate is a carboxylated imidazole agent that undergoes a molecular rearrangement at physiologic pH to grant it greater lipid solubility. Approximately 75% of the drug is plasma protein bound. The free fraction accumulates readily in the CNS. Unconsciousness is produced within one arm-brain circulation. Peak brain concentration is achieved within 1 minute. Redistribution of the drug is quite rapid. A single bolus dose produces hypnosis in 10 seconds and lasts approximately 3 to 5 minutes. Clearance of etomidate is dependent on hepatic blood flow since it has a high extraction ratio and undergoes rapid hydrolysis by the liver with inactive metabolites excreted in the urine.⁹

■ MECHANISM OF ACTION

Etomidate (like barbiturates, propofol, and benzodiazepines) produces dose-dependent CNS depression by modulating GABA receptors to produce hyperpolarization and functional inhibition of

the postsynaptic neurons. GABA antagonists (e.g., flumazenil) may attenuate its effects. **Etomidate has no analgesic properties.**¹⁰

■ PHARMACODYNAMICS

Etomidate produces dose-dependent depression of $CMRO_2$, CBF, and EEG activity analogous to that of the barbiturates. **Etomidate decreases ICP with minimal effect on CPP since it does not affect mean arterial pressure.** It is useful in patients with elevated ICP, especially those who are hemodynamically unstable.¹¹ **Etomidate causes minimal cardiovascular depression, even in the presence of significant cardiac disease.** Heart rate, blood pressure, and cardiac output are adequately maintained. The respiratory depressant effects of etomidate appear to be substantially less than those of thiopental or propofol. This makes etomidate a safer choice than barbiturates in patients with diminished pulmonary function. **Etomidate is therefore considered to be the induction agent of choice in patients with severe cardiopulmonary disease and high-risk patients in whom maintenance of blood pressure is crucial.**¹² Combine etomidate with an opioid analgesic in patients who would be at risk from a transient elevation of blood pressure or heart rate because it does not blunt the sympathetic response to laryngoscopy and intubation.¹³ **Etomidate is the only available IV anesthetic that does not induce the release of histamine and is safe for patients with reactive airways.**¹⁴

■ ADMINISTRATION

Etomidate is formulated in a 0.2% solution with 35% propylene glycol. The standard induction dose is 0.3 mg/kg IV based on total body weight. There is virtually no accumulation of the drug. Emergence time is dose-dependent but remains short even after repeated boluses.¹⁵ Dose adjustments for elderly patients, hepatic disease, or renal disease may be required.

■ ADVERSE EFFECTS

The most common side effects of etomidate are injection site pain, myoclonus, nausea, and vomiting during the induction phase.¹⁶ Myoclonic activity occurs in about one-third of cases and is attributed to interruption of inhibitory synapses in the thalamocortical tract rather than CNS excitation.² Pretreatment with a benzodiazepine, low-dose etomidate, magnesium sulfate, or an opioid analgesic diminishes the frequency of myoclonic movements.¹⁷⁻¹⁹ Vein irritation and pain at the IV site can be attributed to the propylene glycol diluent. Use of a large vein with simultaneous analgesic and saline infusion reduces the incidence of injection pain.²⁰

Etomidate causes a dose-dependent suppression of adrenal corticosteroid synthesis by inhibiting the enzyme 11- β -hydroxylase.²¹ A single induction dose of etomidate temporarily suppresses adrenocortical hormone synthesis.^{22,23} Increased mortality has been attributed to this reduction of endogenous steroids leading to acute adrenocortical insufficiency in critically ill patients on an etomidate infusion.²⁴ **There is currently conflicting evidence as to whether a single induction dose of etomidate affects overall mortality in critically ill patients.**²⁵⁻³¹ Analysis of some studies showed worse outcomes with etomidate use,³²⁻³⁴ whereas other studies showed no difference in mortality with the use of etomidate.^{23,25,26,35-38}

KETAMINE

Ketamine (Ketalar, Ketaject) is a phencyclidine derivative that is unique among induction agents. **It produces a dissociative anesthetic state characterized by profound analgesia and amnesia.** Patients may appear awake with their eyes open and reveal a nystagmic gaze. They may make spontaneous nonpurposeful movements.

Protective reflexes are usually maintained. This is fortunate considering that increased salivation is a common side effect. Ketamine is fast-acting and has a brief duration of action. It has been widely used since 1970 despite emergence delirium limiting the usefulness of this drug.³⁹

■ PHARMACOKINETICS

Ketamine has a pKa of 7.5. Approximately 12% is plasma protein bound. Roughly half of the unbound fraction is available to accumulate rapidly in the CNS. A single induction dose produces anesthesia within 30 seconds and brain concentration peaks at 1 minute. Ketamine follows the three-compartment model with rapid redistribution to the peripheral tissues.³⁹ Its CNS effects last approximately 10 to 15 minutes. Recovery of full orientation and function may take an additional 60 minutes. Ketamine is readily metabolized by hepatic microsomal enzymes to norketamine. Norketamine is one-fourth as potent as its precursor. The active metabolite may explain the prolonged recovery time. Norketamine is hydroxylated and excreted by the kidneys. Ketamine has a high extraction ratio, and its clearance is dependent on hepatic blood flow.²

■ MECHANISM OF ACTION

Ketamine acts by binding to the N-methyl-D-aspartate (NMDA) receptors on postsynaptic neurons. This receptor is a gated ion channel that allows depolarization and initiation of an action potential when activated by glutamate or NMDA. Ketamine blocks the flux of ions through this channel and inhibits the stimulatory effects of these neurotransmitters. Ketamine depresses neuronal activity in the cerebral cortex, depresses the thalamus, and stimulates the limbic system. Analgesia is produced by interrupting the association pathways responsible for the interpretation of painful stimuli that run from the thalamocortical and limbic systems.⁴⁰

■ PHARMACODYNAMICS

Ketamine produces dose-dependent CNS depression. It increases $CMRO_2$ and CBF, leading to an increase in ICP. Ketamine has a potent sympathomimetic effect. Its use often produces an increase in heart rate and arterial blood pressure. It has a direct negative inotropic effect on the myocardium, which is evident in the critically ill patient with depleted catecholamines. Ketamine produces minimal to no respiratory depression and has a potent bronchodilatory effect. It increases both bronchial and oral secretions. Ketamine is likely to preserve protective airway reflexes in contrast to other anesthetic agents. Skeletal muscle tone is increased and results in random movements.³⁹

■ ADMINISTRATION

Ketamine is available in 1% and 5% aqueous solutions for IV administration and a 10% aqueous solution for intramuscular (IM) injection. The induction dose of ketamine is 1 to 2 mg/kg IV over 1 minute or 5 to 10 mg/kg IM.² A lower dose can be used for procedural sedation.⁴¹

Ketamine is indicated for the intubation of asthmatic patients due to its bronchodilatory properties. Ketamine may be therapeutic for these patients because the increase in bronchial secretions may decrease the incidence of mucous plugging.⁴² Ketamine may be useful in the hemodynamically unstable patient due to its cardiac stimulatory effects. **Ketamine does not adversely affect CPP, ICP, intraocular pressure (IOP), mortality, or neurologic outcomes.**⁴³⁻⁵⁰ **It can be used with suspected head trauma or intracranial pathology. Do not use ketamine in patients with ischemic heart disease because it can increase blood pressure, heart rate, and myocardial oxygen demand.**

■ ADVERSE EFFECTS

The most significant side effect of ketamine is the occurrence of postanesthetic emergence reactions.⁵¹ Up to 30% of patients treated with ketamine have reported agitation, aggression, confusion, delirium, hallucinations, hysteria, nightmares, restlessness, and unpleasant sensations.² Those most affected were the elderly, females, and patients receiving more than 2 mg/kg. Children seem less adversely affected than adults. These reactions can be attenuated or eliminated by the coadministration of a benzodiazepine (i.e., midazolam) or propofol.⁵² Other side effects include increased ICP, increased IOP, hypersalivation, nystagmus, and random movements.⁵¹ The hypersalivation may be limited by the administration of atropine or glycopyrrolate.^{53,54} Ketamine may activate epileptogenic foci in patients with a seizure disorder.³⁹ Ketamine can rarely cause an allergic reaction.⁵⁵

PROPOFOL

Propofol (Diprivan) is a sedative-hypnotic agent used for conscious sedation, induction, and maintenance of anesthesia. It has a profile similar to that of thiopental. It is unrelated to any of the other induction agents. The use of propofol has greatly expanded despite its cardiopulmonary depressant effects. It is well suited for ambulatory surgery performed on relatively healthy outpatients. Recovery after propofol anesthesia is rapid and is accompanied by less residual sedation, fatigue, and confusion than any other induction agent. Propofol is associated with a low incidence of postanesthetic emesis.⁵⁶ Propofol as an adjunct to emergency airway management is commonly used for procedural sedation or postintubation sedation.

■ PHARMACOKINETICS

Propofol is an alkyl-phenol compound that is insoluble in water. It is 98% plasma protein bound. Any unbound drug rapidly accumulates in the brain and liver since it is highly lipophilic. A single bolus produces hypnosis in 15 to 45 seconds. Its duration of action is 5 to 10 minutes and reflects a rapid redistribution to lean muscle. Propofol is cleared from the central compartment by hepatic metabolism. Its metabolites are water soluble and excreted in the urine.² It can cause green discoloration of the urine.^{57,58}

■ MECHANISM OF ACTION

Propofol produces CNS depression by modulating the GABA_A receptor by the same mechanism as barbiturates.²

■ PHARMACODYNAMICS

Propofol produces a dose-dependent CNS depression without analgesia. It has a strong amnestic effect. It decreases CMRO₂, CBF, and ICP. Its cardiac depressant effects are greater than those of thiopental. CPP may be affected at high doses. Propofol is a myocardial depressant and potent vasodilator that lowers blood pressure and cardiac output. These effects attenuate the hemodynamic pressor response to laryngoscopy and intubation. Propofol blunts the baroreflex so that heart rate does not increase in proportion to a decrease in blood pressure. Decreased respiratory rate and tidal volume are seen with propofol. The ventilatory response to hypercarbia is diminished. Propofol may produce bronchodilation in patients with chronic obstructive pulmonary disease (COPD).⁵⁹ Propofol appears to have a strong anticonvulsant effect and may be used to terminate status epilepticus.⁶⁰

■ ADMINISTRATION

Propofol is prepared as a 1% oil-in-water emulsion that contains egg lecithin, soybean oil, glycerol, and EDTA. The adult dose for induction is 2.0 to 2.5 mg/kg IV. An infusion rate of 25 to 75 µg/kg/min is

titrated to effect for sedation. Dosages should be reduced to 1.0 to 1.5 mg/kg IV in the elderly, in high-risk patients, and in anyone premedicated with an opioid or a benzodiazepine.⁵⁹ Propofol supports bacterial growth, and any unused portion should be discarded.

■ ADVERSE EFFECTS

Propofol produces pain on injection in up to 75% of patients. This may be reduced or prevented by pretreatment with an opioid or the addition of 0.01% lidocaine to the emulsion. Propofol may cause mild CNS excitation in the form of myoclonus, tremors, or hiccups.² Propofol can rarely cause diabetes insipidus and pulmonary edema.^{61,62}

FOSPROPOFOL

Fospropofol is a prodrug or precursor of propofol used for sedation.^{63,64} It comes as a water-soluble disodium salt. It is dosed at 6.5 mg/kg with additional doses at 1.6 mg/kg. The dosing is based on total body weight. **Propofol is hydrolyzed and rapidly released from the action of alkaline phosphatases on fospropofol.** The hydrolysis of fospropofol also forms phosphate and formaldehyde from the action of the alkaline phosphatases. The formaldehyde is converted into formate. The metabolites (i.e., formaldehyde, formate, and phosphate) do not accumulate to any degree. Fospropofol produces a lower peak plasma concentration of propofol than lipid emulsion propofol. The elimination kinetics of lipid emulsion propofol and fospropofol-derived propofol are the same.

The use of fospropofol has been demonstrated to be safe in clinical studies. The most common adverse effects were self-limited paresthesias and pruritus. It had a different pharmacodynamic and pharmacokinetic profile than lipid emulsion propofol. Fospropofol has a longer elimination half-life of 2 hours and a delayed onset of action. It peaks in 8 minutes. The slower onset of action may cause less hypotension but a longer recovery. The use of water-soluble fospropofol may eliminate the risk of bacterial contamination and lipid-related side effects.

BENZODIAZEPINES

Benzodiazepines are a large class of drugs with anxiolytic, sedative, hypnotic, and amnestic properties without any analgesic properties. Diazepam (Valium), lorazepam (Ativan), and midazolam (Versed) are most often used to facilitate intubation. They have a relatively short time of onset when given IV. Diazepam and lorazepam have longer times of onset, less predictable dose-effect relationships, and longer elimination half-lives when compared to midazolam. Diazepam and lorazepam are insoluble in water and formulated in a propylene glycol diluent. The propylene glycol can produce a high rate of venous irritation and unpredictable absorption after intramuscular injection.⁶⁵ Midazolam is water soluble at a low pH and does not require propylene glycol. This decreases the incidence of erratic absorption after intramuscular injection and pain on injection.

Midazolam is the newest of the three drugs. It has become the standard choice for preinduction anxiolysis, sedation, and amnesia. Midazolam is well suited and widely used as an induction agent.⁶⁶ It may be administered alone or in combination with an opioid. There is considerable hypnotic synergy when midazolam is used in combination with an opioid. The opioids provide excellent analgesia, which is a property lacking in midazolam.² Recovery of consciousness takes longer when midazolam is used as the sole induction agent than when it is used with other single agents (e.g., etomidate, methohexital, propofol, or thiopental). Midazolam is often used as a coinduction agent with ketamine or propofol as it facilitates the onset of anesthesia without prolonging emergence times.²

Midazolam attenuates ketamine's cardiac stimulatory side effects as well as the incidence, severity, and recall of emergence reactions when combined with ketamine.⁶⁷

■ PHARMACOKINETICS

Midazolam is formulated at a pH of 3.5. It is water soluble in an acidic environment. It undergoes a molecular rearrangement that makes it highly lipophilic at a physiologic pH. It is 94% protein bound in the plasma. Unbound midazolam rapidly accumulates in the CNS where it produces dose-dependent sedation or unconsciousness in 30 to 90 seconds. The drug redistributes less rapidly than many of the other hypnotics. This is reflected in the 10- to 30-minute duration of its CNS effects.⁶⁸ Midazolam is oxidized by the liver and excreted in the urine. Changes in hepatic blood flow can influence the clearance of midazolam.⁶⁹ Age has little effect on the elimination half-life.⁶⁹ Fentanyl has been shown to competitively inhibit the hepatic metabolism of midazolam in vitro and to decrease its clearance.⁷⁰

■ MECHANISM OF ACTION

Benzodiazepines bind to a specific site on the alpha subunit of the GABA_A receptor and enhance inhibitory neurotransmission. Midazolam has the greatest affinity for the receptor when compared to other benzodiazepines.² It has been proposed that the percentage of benzodiazepine receptor occupancy accounts for its effects. A 20% occupancy provides anxiolysis. A 30% to 50% occupancy causes sedation. Greater than 60% occupancy produces unconsciousness. It is unknown how the benzodiazepines produce amnesia.²

■ PHARMACODYNAMICS

Midazolam decreases CMRO₂ and CBF like thiopental and propofol. Midazolam has a ceiling effect with respect to cerebral metabolism. The cerebrovascular response to carbon dioxide is unaffected by midazolam. It is a potent anticonvulsant. Midazolam is a mild cardiac depressant and can decrease systemic vascular resistance.⁶⁸ The cardiac output and coronary blood flow are usually not affected by midazolam.⁷¹ The decrease in blood pressure is often masked by the sympathetic response to laryngoscopy. Hypotension may be pronounced in hypovolemic patients or in those who were given large doses.

Midazolam's respiratory effects have a ceiling. It produces a mild and dose-dependent respiratory depression. The respiratory depression is insignificant in relatively healthy patients. The respiratory depression is enhanced in patients with pulmonary disease. Hypoxemia is more frequent in patients who receive midazolam in combination with an opioid than in patients who receive either drug alone.⁷²

■ ADMINISTRATION

An induction dose of midazolam is 0.2 to 0.4 mg/kg IV. The dose of midazolam is reduced to 0.1 to 0.2 mg/kg when used as a coinduction agent. The dose for sedation is 0.04 to 0.1 mg/kg IV. It can be administered intramuscularly at a dose of 0.07 to 0.1 mg/kg when rapid onset is not required.² Doses may have to be lowered in older patients because sensitivity to the hypnotic effects of midazolam increases with age independent of pharmacokinetic factors.⁷³

■ ADVERSE EFFECTS

Midazolam has relatively few adverse effects. It is a mild cardiorespiratory depressant. A synergistic respiratory depressant effect may result in hypoxemia, apnea, and death when it is combined with an opioid. Monitor patients receiving this combination with pulse oximetry while being given supplemental oxygen.⁷² Midazolam produces little venous irritation and pain on injection. It may

precipitate a psychotic episode in patients taking valproate. It does cross the placenta and is associated with birth defects when administered in the first trimester.⁶⁸ Paradoxical reactions (e.g., aggression, agitation, confusion, delirium, hysteria, and restlessness) can be treated and reversed with flumazenil.⁷⁴⁻⁷⁶

OPIOIDS

Opioids produce dose-dependent analgesia, sedation, and respiratory depression by mimicking the effects of endogenous opiopeptides.⁷⁷ Morphine is the standard to which all opioids are compared. Fentanyl (Sublimaze) is the opioid of choice due to its rapid onset and short duration of action.⁷⁸ It has been in use since 1968, and its effects are well documented. **Fentanyl is rarely associated with a significant release of histamine.**⁷⁹ Fentanyl has a remarkable hemodynamic stability profile.⁷⁹ Fentanyl will produce anesthesia adequate for intubation if a large dose is given. It is more often used as a sedative-analgesic or as a pretreatment adjuvant with one of the previously mentioned induction agents. Fentanyl is a synthetic opioid that is 50 to 100 times more potent than morphine. It is structurally related to the phenylpiperidines. Fentanyl is highly lipophilic and produces excellent short-term analgesia and sedation.²

Alfentanil (Alfenta) is a structural derivative of fentanyl. It has a more rapid onset of action than fentanyl and half the duration of effect. Alfentanil is between one-sixth and one-ninth as potent as fentanyl. Its uses are analogous to those of fentanyl. It has been in use in the United States since 1982.⁸⁰ Alfentanil is safe and effective for use in emergent rapid sequence intubation.⁸¹ It was associated with greater cardiovascular depression than fentanyl in cardiac patients.⁸² Alfentanil is associated with a greater incidence of nausea and vomiting than fentanyl.⁸³ There are no data to suggest that alfentanil is more efficacious than fentanyl.

■ PHARMACOKINETICS

Plasma fentanyl is 85% protein bound. Its lipophilic nature allows it to enter highly perfused tissues rapidly (e.g., the brain, heart, and lungs). Single bolus dose effects may be seen in as little as 10 seconds and peak in 3 to 5 minutes. Morphine's effects peak in 20 to 30 minutes. Fentanyl has a high affinity for adipose tissue, and redistribution accounts for the cessation of effects, which can take up to 30 to 60 minutes. An equipotent dose of morphine has a duration of 3 to 4 hours. Redistribution of fentanyl from peripheral tissues to the central compartment after large or repeat doses may prolong its effects. Clearance of morphine and fentanyl is by hepatic metabolism. These drugs have a high extraction ratio, and changes in hepatic blood flow can influence the clearance of fentanyl.⁸⁰

■ MECHANISM OF ACTION

Fentanyl binds to the μ (mu) opioid receptor found throughout the CNS. Activation of the opioid receptor causes hyperpolarization and inhibition of neurotransmitter release.⁷⁷ It has been suggested that fentanyl may be a low-affinity NMDA receptor antagonist.⁸⁴

■ PHARMACODYNAMICS

Fentanyl decreases CBF and cerebral oxygen consumption. A relatively small dose of 3 μ g/kg produced an elevation of ICP in patients with head trauma.⁸⁵ Fentanyl may produce a mild reduction in heart rate with little effect on cardiac contractility. Systemic vascular resistance and blood pressure may be slightly reduced. They are usually unaffected in patients without cardiac pathology.⁸⁶ Respiratory depression induced by fentanyl is dose dependent. The respiratory rate decreases, followed by the tidal volume and subsequent apnea. The patient's response to hypercarbia is blunted when sedated with fentanyl.⁸⁷

■ ADMINISTRATION

Fentanyl can be used in several ways to facilitate emergency intubation. As little as 3 to 5 µg/kg IV over 2 minutes may allow for an awake intubation when given purely for analgesia. Incremental doses of fentanyl from 25 to 50 µg in adults can be titrated to produce the desired effect.² Fentanyl has a more stable hemodynamic profile during rapid sequence intubation than either thiopental or midazolam.⁷⁸ Between 5 and 15 µg/kg of fentanyl may be used as the sole induction agent in hemodynamically unstable patients and those with poor cardiac reserve.⁷⁸

The most prudent role for fentanyl is as an adjunct to an induction agent. Premedication 3 minutes prior to intubation with 2 to 4 µg/kg of fentanyl IV over 2 minutes provides excellent analgesia, attenuates the transient hypertension, and attenuates tachycardia associated with laryngoscopy and intubation.⁸⁸ Compared with lidocaine and beta-blockers, opioids are more effective at blunting the pressor response, are more reliable, and do not produce rebound hypotension and bradycardia.^{89,90}

■ ADVERSE EFFECTS

Respiratory depression is common to all opioids. Fentanyl has relatively few adverse side effects. Nausea and vomiting are relatively uncommon when compared to other opioids.² Fentanyl is not associated with a significant release of histamine, which is reflected in its hemodynamic stability. Muscular rigidity involving the chest wall and diaphragm may occur.⁹¹ This makes ventilation difficult if it occurs. This happens more often at doses greater than 15 µg/kg. It may be prevented or relieved by neuromuscular blockade or by opioid antagonism with naloxone.^{91,92} Myoclonic movements may occur and do not reflect seizure activity on the EEG. Biliary colic and urinary retention are associated with fentanyl administration.²

NEUROMUSCULAR BLOCKING AGENTS

Neuromuscular blockade is an integral part of the rapid sequence induction and intubation protocol (Tables 12-2 and 12-3). The combination of a paralytic agent and a sedative or analgesic is superior to the use of any single agent. The use of a neuromuscular blocking (NMB) agent to facilitate intubation provides for control of the airway and better visualization of the vocal cords than does sedation without paralysis.^{93,94} It is well documented that rapid sequence induction with an NMB agent allows for faster intubations with fewer complications than sedation alone.¹ Reserve the use of a sedative without an NMB for the awake oral intubation of a patient with a difficult airway.

NMBs are classified as either depolarizing or nondepolarizing depending on their action at the nicotinic acetylcholine receptor of the motor end plate. **The optimal NMB agent has a rapid onset of action, a predictably short duration of action, and no side effects. The optimal NMB agent has yet to be found.** Succinylcholine (Anectine) and rocuronium (Zemuron) remain the standard NMB agents for Emergency Department intubations.^{95,96}

SUCCINYLCHOLINE

Succinylcholine is the only depolarizing NMB agent in clinical use. It was introduced in 1952 and is a chemical combination of two acetylcholine molecules. **It is one of the most widely used NMB agents in the Emergency Department because its onset of action is faster and its duration of action is shorter than that of any other NMB agent. This is particularly important in patients who cannot be intubated after neuromuscular blockade and when the resumption of spontaneous respirations is vital.**

■ PHARMACOKINETICS

Adequate intubating conditions are usually achieved in 60 seconds after a paralytic dose of succinylcholine.⁹⁷ The duration of apnea following a single dose of succinylcholine is 3 to 5 minutes and reflects the rapid degradation of the drug by pseudocholinesterase (i.e., also known as plasma cholinesterase or butyrylcholinesterase).⁹⁷ Repeated doses or infusions of succinylcholine may produce tachyphylaxis, prolonged paralysis, and repolarization of the neuromuscular membrane (i.e., phase II block).⁹⁷ A phase II block can be partially reversed by administration of an anticholinesterase agent similar to the reversal of a nondepolarizing block. **A nondepolarizing agent can be administered after the patient is intubated if paralysis of greater than 3 to 5 minutes is desired.**

■ MECHANISM OF ACTION

The structure of succinylcholine allows it to bind noncompetitively to acetylcholine receptors and cause depolarization of the postjunctional neuromuscular membrane. The initial depolarization is a brief period of muscle fasciculation following the administration of the drug. Acetylcholine is hydrolyzed within milliseconds. Succinylcholine remains intact for several minutes. It produces paralysis by occupying the acetylcholine receptors and makes the motor end plates refractory so that muscle contraction cannot occur. Muscle relaxation proceeds from the distal muscles to the proximal muscles. The diaphragm is one of the last muscles to become paralyzed.⁹⁸

■ PHARMACODYNAMICS

Succinylcholine is rapidly hydrolyzed by plasma pseudocholinesterase to succinylmonocholine. Only a small fraction of the IV administered dose reaches the neuromuscular junction. Succinylmonocholine has some neuromuscular blocking properties and is further hydrolyzed to succinic acid and choline. These end products are rapidly taken up by cells and reused in various biochemical molecules. The rapid degradation of succinylcholine provides a concentration gradient that causes the diffusion of succinylcholine away from the acetylcholine receptors and allows repolarization of the myocyte membrane.

Some patients have an atypical pseudocholinesterase enzyme. This condition occurs with an incidence of 1 in 3200. This is a genetic variant with autosomal semidominant transmission. The duration of action of succinylcholine is markedly prolonged due to decreased enzyme activity. A single intubating dose of succinylcholine may last up to 8 hours in patients who are homozygous for the atypical allele.⁹⁸

■ ADMINISTRATION

The recommended dose of succinylcholine to produce optimal intubating conditions is 1.0 to 1.5 mg/kg IV bolus in adults and 1.5 to 2.0 mg/kg in infants with the increased dose explained by their higher volume of distribution.^{97,99} These doses are based on total body weight and not ideal body weight like rocuronium. Increase this dose by 50% in patients who have received a defasciculating dose of a nondepolarizing NMB prior to the administration of succinylcholine.⁵³ IM administration is possible and is important for use in an emergency when control of the airway is necessary and the patient has no IV access. The IM dose is two to four times the IV dose.^{100,101}

■ ADVERSE EFFECTS

Numerous potential adverse effects are associated with the administration of succinylcholine but occur relatively uncommonly. These include anaphylaxis, autonomic stimulation, elevated ICP and IOP, histamine release, hyperkalemia, malignant hyperthermia,

muscular fasciculations and myalgia, and prolonged apnea.^{97,102} **The use of succinylcholine is recommended for rapid sequence induction and intubation because the risk of a compromised airway far outweighs the potential harm from these side effects.**

The fine, chaotic muscle contractions that are often observed at the onset of paralysis are associated with several side effects. They are most commonly associated with myalgia, increased IOP, increased ICP, and increased intragastric pressure. Muscle pain 24 to 48 hours after the administration of succinylcholine is most prominent in young muscular men. Muscle pain is unlikely in children, the elderly, and those with undeveloped or diminished muscle mass. Muscle fasciculations may be prevented by the administration of a defasciculating dose (i.e., 10% of the paralytic dose, a phenomenon known as “precuarization”) of a nondepolarizing NMB agent given 3 to 5 minutes prior to the succinylcholine.¹⁰³

Increased ICP may occur with the use of succinylcholine. The magnitude and clinical significance of this increase remain unclear. Defasciculation with a nondepolarizing NMB agent has been shown to prevent this rise in ICP.¹⁰⁴

Omitting the use of a paralyzing agent entirely during the rapid sequence induction of patients with penetrating eye injuries or intracranial pathology for fear of the potential increase in IOP or ICP is a decision that must be made for each individual patient. Any attempt to intubate a nonparalyzed and lightly anesthetized patient could result in gagging or “bucking.” This patient action has been shown to increase IOP and ICP far more than would be achieved from an intubating dose of succinylcholine. **Muscle fasciculations are benign and precuarization is unnecessary in most patients.** It is prudent to use a nondepolarizing NMB agent or use precuarization with succinylcholine to prevent worsening of an injury in patients with eye injuries or suspected intracranial pathology.¹⁰⁵ Rocuronium is a nondepolarizing agent that has been shown to significantly decrease IOP during rapid sequence induction.¹⁰⁶ Its use may be indicated in patients with penetrating eye injuries.¹⁰⁶

Increased intragastric pressure is lessened by precuarization. Increased intragastric pressure may increase the risk of aspiration. Succinylcholine favorably increases the tone of the lower esophageal sphincter and may mitigate the risk of aspiration.¹⁰⁷ Regurgitation of stomach contents during intubation is more likely the result of distention from overzealous mask ventilation.

Succinylcholine binds to acetylcholine receptors throughout the body including those of the autonomic ganglia. Succinylcholine may have direct muscarinic effects on the heart. It is difficult to characterize a specific cardiovascular effect typical of succinylcholine. It may produce tachycardia, bradycardia, or dysrhythmias.⁹⁷ Children are particularly susceptible to bradycardia following succinylcholine administration. Consider giving children 0.01 mg/kg IV of atropine prior to administration of succinylcholine.¹⁰⁰

Prolonged apnea following succinylcholine administration is a sign of decreased plasma pseudocholinesterase levels. This may occur in patients with hepatic disease, anemia, renal failure, cancer, connective tissue disorders, pregnancy, cocaine intoxication, or genetically deficient enzyme activity or patients taking cytotoxic drugs. Most cases of prolonged apnea rarely exceed 20 minutes.¹⁰⁸

Succinylcholine may produce an increase in serum potassium level, which is typically less than 0.5 meq/L. Use it with caution in patients with significant hyperkalemia. Its use is not contraindicated in patients with renal failure, but caution must be taken if their serum potassium level is elevated. It has been associated with cases of massive hyperkalemia (e.g., > 5 meq/L) and cardiac arrest in patients who have had digoxin toxicity, myasthenia gravis, massive muscle trauma, crush injuries, severe burns, and major nerve or spinal cord injury at least 1 week prior to receiving succinylcholine.^{95,97} Do not use succinylcholine starting 24 hours after the insult in these patients.

■ MALIGNANT HYPERTHERMIA

Malignant hyperthermia (MH) is an extremely rare and life-threatening autosomal dominant condition that can develop following exposure to certain inhaled anesthetics and/or succinylcholine in genetically susceptible individuals. It is characterized by intense, sustained skeletal muscle contraction leading to severe acidosis, rhabdomyolysis, hyperthermia, hyperkalemia, arrhythmias, and death if left untreated. The triggering exposure is not dose dependent. It can occur following any single dose or combination of offending agents. It may occur in individuals who have been exposed to the agents in the past without an adverse effect. The incidence of MH during anesthesia is estimated to be 1 in 15,000 in children and 1 in 50,000 in adults.¹⁰⁹ **MH is most notoriously characterized by a rapid elevation in temperature. The earliest signs of the condition are usually profound tachycardia, tachypnea, and generalized skeletal muscle rigidity.** Laboratory blood analysis reveals severe respiratory and metabolic acidosis, hyperkalemia, and elevation of serum creatine kinase.

Early and aggressive treatment is the key to patient survival. This involves active cooling measures, volume resuscitation, correction of acid-base and electrolyte disturbances, and rapid administration of dantrolene in a 2 to 3 mg/kg IV bolus with additional increments up to 10 mg/kg.^{97,109} Dantrolene sodium is a muscle relaxant that is supplied as a lyophilized powder in 20 mg vials. Each vial must be reconstituted with 60 mL of water.¹⁰⁹ **Early administration of dantrolene is important to abort the reaction and greatly increases the chance of survival. Continue dantrolene administration until all signs of MH have stabilized.** Admit the patient to the intensive care unit for observation of any recurrence following the acute phase.

Isolated masseter muscle rigidity is a benign side effect in most cases. It has been reported mainly in children receiving succinylcholine. Masseter muscle rigidity was the first sign of an abnormal reaction in several reported cases of fatal MH.¹¹⁰ **Masseter rigidity following the administration of succinylcholine requires the patient to be closely monitored for other signs of MH.**

Patients of families with MH, those with suspected reactions, and other selected high-risk patients can undergo a muscle biopsy test known as the caffeine-halothane contracture test. The test carries a 100% sensitivity and 85% to 90% specificity for MH susceptibility.¹⁰⁹ Refer patients who develop suspected MH reactions immediately to their primary physicians for testing and follow-up. Documented positive susceptibility and patient education could prevent a future potentially lethal exposure to offending agents.

The benefits of intubation with a rapidly acting and short-lasting paralytic agent such as succinylcholine provide the safest conditions for intubation despite the lengthy list of potential adverse effects. Administer a nondepolarizing agent for maintenance following intubation with succinylcholine if prolonged paralysis is required.

NONDEPOLARIZING AGENTS

Nondepolarizing NMB agents act by competitive inhibition of the acetylcholine receptors at the motor end plate. They weakly bind to the receptor and block the binding site for acetylcholine without producing any effect on the postsynaptic neuromuscular membrane. This blockade is dependent on the relative concentrations of acetylcholine and NMB available in the synaptic cleft. It follows the kinetics of competitive inhibition. Normal neuromuscular transmission is restored as the ratio returns in favor of acetylcholine. Return of muscle function can be hastened with a cholinesterase inhibitor (e.g., neostigmine or edrophonium) after some muscular contraction is observed. **Nondepolarizing agents have**

the potential for reversal and fewer side effects than succinylcholine. Their longer time to onset and much longer duration of action make them less useful for rapid sequence intubation.⁹⁷

Nondepolarizing NMB agents can be grouped by chemical structure. The steroid-based agents include pancuronium, vecuronium, and rocuronium. The oldest nondepolarizing agent is d-tubocurarine. Atracurium, cisatracurium, d-tubocurarine, and mivacurium are benzylisoquinolines.⁹⁷ Pancuronium, vecuronium, and rocuronium have been extensively studied for use in rapid sequence intubation.¹¹¹ Rocuronium (Zemuron) has become established as the nondepolarizing NMB of choice for rapid sequence intubation in situations where succinylcholine is contraindicated. Rocuronium is discussed separately from the other nondepolarizing NMB agents.

Rocuronium

Rocuronium has been used at a dose of 1.2 mg/kg based on ideal body weight when the avoidance of succinylcholine is desired during rapid sequence intubation. This dose is twice the standard intubating dose to yield an onset of action in approximately 60 seconds and intubating conditions that are comparable to succinylcholine.^{112,113} Dosing by total body weight will result in a longer duration of action.¹¹⁴ This has been demonstrated in adult and pediatric populations.^{112,115} The increased dosage of 1.2 mg/kg prolongs the duration of action to greater than 1 hour, which far exceeds the 3 to 5 minutes provided by succinylcholine.^{97,116} The nondepolarizing competitive blockade produced by rocuronium cannot be immediately reversed by anticholinesterases (e.g., neostigmine) until partial competitive antagonism by acetylcholine has taken place naturally at the motor end plate. This may take an average of 20 minutes to occur. It must be measured by the return of muscular twitch using a neuromuscular twitch monitor often used by Anesthesiologists in the Operating Room to monitor the level of intraoperative motor blockade.¹¹⁵ **Selective reversal of the dense rocuronium paralysis with the newly Food and Drug Administration-approved agent sugammadex if unexpected difficulties with intubation or ventilation are encountered should be considered. Staff experienced in a surgical airway must be immediately available if intubation and ventilation fail and complete reversal to the point of return of adequate spontaneous ventilation proves unsuccessful.**

■ PHARMACOKINETICS

Rocuronium is eliminated primarily by the liver, and < 10% is eliminated by the kidneys.⁹⁷ Its duration of action is significantly prolonged in liver failure and only slightly in renal failure. There are no active metabolites. Nondepolarizing NMB agents as a class are highly ionized, water-soluble compounds that cannot easily cross lipid membranes (e.g., the blood-brain barrier and the placenta). They have no CNS effects and do not affect the fetus when administered to pregnant women.⁹⁷

■ MECHANISM OF ACTION

Rocuronium binds nicotinic acetylcholine receptors at the neuromuscular end plate. It is unable to induce the conformational change necessary to open the ion channels and allow subsequent depolarization. This results in a competitive and antagonistic block.

■ PHARMACODYNAMICS

Several drugs (e.g., aminoglycosides, certain antiarrhythmics, dantrolene, lithium, magnesium, and volatile anesthetics) will augment the neuromuscular blockade produced by nondepolarizers. Corticosteroids, certain anticonvulsants, and calcium will diminish the effect of NMBs. Patients with myasthenia gravis, Lambert-Eaton myasthenic syndrome, and Duchenne's muscular dystrophy exhibit

varying sensitivity to nondepolarizing NMBs. Burn patients are resistant to their effects. Careful titration of dosages, dosing intervals, and infusion rates is necessary in these patient populations.

■ ADMINISTRATION

Rocuronium is administered at a usual intubating dose of 0.6 mg/kg. It provides a clinical duration of roughly 45 minutes. Rapid sequence intubation with rocuronium is most rapidly achieved with a dose of 1.2 mg/kg based on ideal body weight and is associated with an accompanying increase in duration when compared to the 0.6 mg/kg dose.¹¹⁴ Dosing by total body weight can increase the duration of action.¹¹⁴ Maintenance of paralysis following intubation can be achieved with intermittent 0.1 mg/kg boluses or by infusion rates of 5 to 12 mcg/kg/min titrated to effect.

■ ADVERSE EFFECTS

Rocuronium is essentially devoid of any serious side effects other than the potential for a severe anaphylactic reaction in allergic patients.^{102,117,118} This should not be taken lightly. NMBs are responsible for > 50% of all life-threatening anaphylactic or anaphylactoid reactions occurring during anesthesia administration.⁹⁷ Although succinylcholine is the most common offending agent, the nondepolarizers are second.

The steroidal nondepolarizers possess varying degrees of vagolytic activity and are not associated with histamine release. The vagolytic action of rocuronium is weak and rarely of clinical significance, in contrast to pancuronium, another steroidal nondepolarizer, which can cause significant tachycardia following administration. Patients may report pain on injection of rocuronium due to venous irritation. This can be reduced by prior administration of IV lidocaine but is usually not a problem because patients are unconscious or sedated at the time of rocuronium injection.

Other Nondepolarizing Agents

Pancuronium is classified as a long-acting, bisquaternary steroidal nondepolarizing agent. It produces paralysis in 2 to 5 minutes and lasts approximately 60 to 90 minutes at a dose of 0.08 to 0.12 mg/kg. Supplemental doses of 0.02 mg/kg following intubation can be given intermittently to maintain paralysis.⁹⁷ Its use is associated with an increased heart rate, blood pressure, and cardiac output through a postganglionic vagolytic effect. It is not associated with the release of histamine. An estimated 80% to 85% of a dose of pancuronium is eliminated unchanged in the urine. Patients with renal failure may find its duration significantly prolonged.⁹⁷ The low cost of pancuronium and familiarity have made it popular. Its slow onset of action and extended duration limit its usefulness in facilitating emergent endotracheal intubation.

Removing a quaternary methyl group from pancuronium yields the monoquaternary steroidal nondepolarizer vecuronium. This small change does little to affect potency. It favorably alters the side effect profile of the drug, most notably the vagolytic action. The vagolytic effects of vecuronium are similar to those of rocuronium, are negligible, and do not cause histamine release. Vecuronium can cause anaphylaxis.¹⁰² This molecular change alters the metabolism and excretion of the drug when compared with pancuronium. Vecuronium is metabolized to a small extent by the liver and depends primarily on biliary excretion and secondarily on renal excretion. Vecuronium is unstable in solution. It is prepared as a lyophilized powder that must be hydrated prior to use.

The normal intubating dose of vecuronium at 0.1 mg/kg takes 3 minutes to produce adequate paralysis for intubation. The patient will remain apneic for 30 to 35 minutes after an intubating dose of vecuronium. It can produce good intubating conditions within

1 minute at 2.5 times the normal dose. This results in paralysis for 1 to 2 hours. Maintenance of paralysis can be achieved with boluses of 0.02 mg/kg. The most troublesome side effect of this drug is prolonged paralysis up to several days following an infusion. This prolonged action is possibly a result of accumulation of its active 3-hydroxy metabolite.⁹⁷

Rapacuronium is a newer nondepolarizing NMB agent with onset times and duration of action similar to those of succinylcholine. It was developed as a replacement for succinylcholine in the rapid sequence protocol. Rapacuronium was voluntarily withdrawn from the U.S. market by its manufacturer in 2001 due to reported incidences of fatal bronchospasm.

Succinylcholine and rocuronium are the muscle relaxants of choice for rapid sequence emergency intubations.¹¹⁹

MISCELLANEOUS AGENTS

LIDOCAINE

Lidocaine is a local anesthetic agent that has an antiarrhythmic effect on the heart. A dose of 1 to 2 mg/kg IV attenuates the increases in blood pressure, heart rate, ICP, and tachycardia associated with laryngoscopy.¹²⁰⁻¹²³ It does not affect myocardial contractility in therapeutic doses. Lidocaine is usually administered to patients in whom the increases in blood pressure, heart rate, and ICP associated with direct laryngoscopy are undesirable.

ATROPINE

Atropine is a rapidly acting muscarinic acetylcholine receptor antagonist with significant vagolytic effect. It is commonly used as part of the Advanced Cardiac Life Support (ACLS) protocol during resuscitation of patients in cardiac arrest and those with symptomatic bradycardia at doses of 1.0 mg and 0.50 mg IV, respectively. Atropine is given during rapid sequence intubation of children using succinylcholine to prevent significant bradycardia and possibly asystole, which may occur much more frequently than in adults.¹²⁴ The dose is 0.01 mg/kg IV with a minimum dose of 0.10 mg IV and a maximum dose of 0.40 mg IV. Atropine has a secondary antisialagogue effect of reducing secretions produced in the respiratory tract and the salivary glands.

Atropine crosses the blood-brain barrier, and overdoses may lead to central atropine intoxication (i.e., central anticholinergic syndrome). This is characterized by agitation, restlessness, confusion, and hallucinations that may progress to stupor, seizures, and coma. Provide supportive treatment (e.g., seizure prophylaxis and mechanical ventilation). Reversal of this life-threatening condition can be achieved with IV physostigmine (i.e., an anticholinesterase agent with the ability to cross the blood-brain barrier).

GLYCOPYRROLATE

Glycopyrrolate is a quaternary amine of the muscarinic anticholinergic class.¹²⁵ It possesses significantly less of a vagolytic effect but greater antisialagogue effects when compared to atropine. **This makes it the drug of choice for premedication to reduce pharyngeal and tracheobronchial secretions.** Glycopyrrolate does not easily cross the blood-brain barrier due to its quaternary ammonium structure and makes the occurrence of central anticholinergic side effects much less likely. Do not administer glycopyrrolate to neonates due to the benzyl alcohol component, which can cause significant adverse effects. The recommended antisialagogue dose of glycopyrrolate is 0.004 mg/kg IM given 30 to 60 minutes prior to the intubation. It may be administered IV in boluses of 0.1 mg every 2 to 3 minutes as needed until the desired effect. It usually requires one

or two doses during procedural sedation as an adjunct to prevent ketamine's effect of increasing respiratory tract secretions.

Glycopyrrolate is routinely administered with anticholinesterase medications during reversal of nondepolarizing neuromuscular blockade to counteract the unwanted side effects of bradycardia, bronchoconstriction, and intestinal hypermotility that accompany the ensuing increase in cholinergic activity.¹²⁵ It is administered along with neostigmine and pyridostigmine at a dose of 0.2 mg IV of glycopyrrolate for each 1 mg of neostigmine or 5 mg of pyridostigmine.¹²⁵ The onset is usually within 1 minute when given IV. The duration of the vagolytic and antisialagogue effects are 2 to 3 hours and up to 7 hours, respectively, when given IV.

DEXMEDETOMIDINE

Dexmedetomidine is a centrally acting α_2 -adrenergic agonist similar to clonidine but with more selectivity for the α_2 receptor.¹²⁶ It causes dose-dependent sedation and anxiolysis and blocks the sympathetic response to stress and airway manipulation. It is increasingly being used with much success as an adjunct to awake fiberoptic intubation.¹²⁷ Its main indication is for sedation of intubated and mechanically ventilated patients.¹²⁸ Patients remain calm and sedated when left alone but are readily arousable when stimulated and follow commands.¹²⁶ Dexmedetomidine causes little to no respiratory depression and tachycardia.¹²⁹ The main side effects are hypotension and bradycardia.^{130,131} Dosing consists of an initial loading dose of 1 mcg/kg IV in adults and 0.5 to 1 mcg/kg in children over 10 minutes followed by an infusion of 0.2 to 0.7 mcg/kg/hr titrated to the desired level of sedation.^{132,133} Its half-life is about 6 minutes due to rapid redistribution. This short half-life has the potential for its use in awake intubations. It can be used for sedation in the magnetic resonance imaging scanner at 2 mcg/kg IV followed by an infusion of 1 mcg/kg/hr or 1 to 2 mcg/kg IM.^{134,135}

SUGAMMADEX

Sugammadex (Bridion) is a novel agent that can terminate a dense neuromuscular block due to rocuronium or vecuronium.¹³⁶⁻¹⁴² The recommended dose of 16 mg/kg based on total body weight can completely reverse a single dose of 1.2 mg/kg of rocuronium in as little as 2 to 2.5 minutes.^{139,143-150} The drug is a cyclodextrin compound or a cyclic oligosaccharide carbohydrate that is formed from the degradation of starch.¹⁵¹ It has a hydrophobic core surrounded by a hydrophilic outer rim. The hydrophobic core can trap other hydrophobic substances, encapsulate them, and render them inactive. Cyclodextrins administered IV are not metabolized and are excreted substantially by the kidney. The usual elimination half-life of 2 hours can be greatly prolonged up to 19 hours in patients with severe renal impairment, and use of the drug is not recommended in this patient population.^{144,149,150}

Sugammadex is the first agent of its class. It was recently approved by the Food and Drug Administration for use in the United States. It has been used in Europe for several years. It has an affinity for the aminosteroid nondepolarizing NMB agents and has no interaction with succinylcholine or the benzylisoquinolone NMB agents (e.g., cisatracurium). Its affinity is strongest for rocuronium, followed by vecuronium then pancuronium.¹⁵¹ It binds rocuronium in a 1:1 fashion to decrease rocuronium plasma concentrations.¹⁵¹ Bound rocuronium cannot gain access to the motor end plate and cause paralysis. The reversal of the neuromuscular block results from the binding of plasma rocuronium and the rapid movement of rocuronium from peripheral sites to the plasma to maintain an equilibrium. The sugammadex-rocuronium complex is excreted in the urine.

A variety of adverse events have been reported with the use of sugammadex. The most significant are anaphylactic reactions

(0.3%), prolonged QT interval, and marked bradycardia occasionally resulting in cardiac arrest.¹⁴⁴ Sugammadex results in more hemodynamic stability than neostigmine.¹⁵² The most common adverse reactions in > 10% of patients are vomiting, pain, nausea, hypotension, and headache.¹⁴⁴ Increases in the prothrombin time and international normalized ratio of up to 25% for up to 1 hour have been seen following a dose of 16 mg/kg. The clinical significance of this is uncertain. Studies in surgical patients have not demonstrated an increased risk of bleeding due to this effect.^{144,149,150} It is recommended that coagulation parameters be carefully monitored in patients at risk for bleeding and in those being treated with anticoagulation. It is recommended that close monitoring of respiratory function be performed following reversal with sugammadex, although recurarization is unlikely following a dose of 16 mg/kg.^{144,149,150} Sugammadex can cause bronchospasm in patients with an underlying pulmonary disease.¹⁵³ This drug exerts no action at nicotinic or muscarinic receptor sites. Muscarinic side effects (e.g., bradycardia and bronchoconstriction) are less likely.^{144,149} Sugammadex binds to bone and teeth. The effect of this is unknown in growing children. The safety and efficacy of sugammadex have not been established in patients < 18 years of age. Despite this, it is safer than neostigmine.¹⁵⁴

Sugammadex binds to and decreases plasma levels of other drugs with a steroid-based structure (e.g., hormones and oral contraceptives), rendering them ineffective. It is recommended that patients using hormonal contraceptives use an additional nonhormonal method of contraception for 7 days following administration of sugammadex.¹⁴⁴ Another drug interaction worth noting is with the oral estrogen receptor modulator toremifene. It may delay recovery with sugammadex in patients taking this medication.^{144,149} There is no effect of sugammadex on cortisol and progesterone.¹⁵⁵ Sugammadex temporarily increases aldosterone and testosterone.¹⁵⁵

Sugammadex has the potential for significant use in the Emergency Department. The biggest concern with using rocuronium for intubation is the length of time a patient is paralyzed if they cannot be intubated or ventilated. The development and availability of sugammadex provide a “safety net” to reverse rocuronium’s effects in these situations.¹⁵⁴ **Sugammadex may eventually allow rocuronium to become the NMB agent of choice for rapid sequence intubation in the Emergency Department.**

Sugammadex can reverse rocuronium. The patient may still have the indications for airway management and ventilator management. Use of aminosteroid NMBs (i.e., pancuronium, rocuronium, and vecuronium) after sugammadex is very difficult. The use of isoquinoline NMBs (i.e., atracurium, cisatracurium, and mivacurium) and succinylcholine after sugammadex works well.

SUMMARY

Numerous pharmacologic agents are available to sedate, relax, and paralyze a patient in preparation for intubation. These same agents are used in lesser doses to maintain postintubation sedation and paralysis as well as for procedural sedation. There is no ideal sedative or paralytic agent. The combination of lesser doses of several agents will maximize the positive effects and minimize the adverse effects of each individual drug. This requires Emergency Physicians to become familiar with several drugs in each class so they may choose the appropriate combination for each patient.

Endotracheal Medication Administration

Megan Johnson and Shoma Desai

INTRODUCTION

Health care providers are charged with the primary goal of optimizing the oxygenation, ventilation, and hemodynamic status of the patient during a resuscitation. In most cases, the first definitive intervention is to secure the airway through endotracheal (ET) intubation. The establishment of access to the systemic circulation soon follows. **Vascular access in certain patients can be problematic, and the ability to administer medications endotracheally can be lifesaving.**

The ET route of medication administration was first reported in 1857 for the alveolar absorption of curare in dogs.¹ This was followed in 1884 by the observation that ET instilled salicylates appeared in the urine.² The ET application of strychnine, atropine, chloral hydrate, and potassium iodide was studied in 1897.² The first suggestion to use the ET route for the therapy of pulmonary disease was made in 1915.³ This idea resulted in a study in 1937 that recommended the use of inhaled epinephrine in asthmatics.⁴ The rapidity of pulmonary absorption was eventually used for resuscitation purposes. In 1967, the equality of the ET, intravenous (IV), and intracardiac routes of epinephrine administration in the resuscitation of hypoxia-induced cardiorespiratory arrest in dogs was demonstrated.⁵ This study prompted the routine use of

the ET route for medication administration in emergent clinical situations.

The ideal drug delivery system to the lungs does not yet exist. It would have the following characteristics. Medications are aerosolized to a fine mist to increase the absorption through the alveoli. Avoid adherence of medication to the ET tube. Delivery to the lungs and not the bronchi, trachea, or ET tube. No risk of splash-back. No need to stop compressions or ventilations of cardiopulmonary resuscitation (CPR). We have achieved some of these characteristics.

ANATOMY AND PATHOPHYSIOLOGY

Most experiments involving ET medication administration have been conducted on subjects with normal cardiovascular function. There are still many questions remaining about the utility of this route in patients with cardiopulmonary arrest. The alveolar-capillary membrane is a highly absorptive surface. Numerous factors can undermine this potential. These include reduced pulmonary blood flow (e.g., less than 30% of normal during CPR), ventilation-perfusion mismatch, and compromised alveolar absorption (e.g., from pulmonary edema) in cardiopulmonary arrest.⁶⁻⁸

ET-administered medications are absorbed in a protracted manner during a cardiopulmonary arrest. This is termed the “depot effect” and is observed in laboratory and clinical experiments.⁶ A study of 2 mg/kg ET lidocaine in nonarrest patients revealed a biphasic pattern of absorption, with an initial immediate peak and a second higher peak approximately 24 minutes later.⁹ Plasma lidocaine levels were still measurable 120 minutes after instillation.⁹ The relatively low initial and subsequent extended plateau of plasma medication levels is also exhibited by the ET administration of atropine, epinephrine, and vasopressin.^{6,10} Local vasoconstriction induced by epinephrine may further contribute to this “depot effect.”¹¹

MEDICATION DOSE

The American Heart Association (AHA) recommends an ET medication dose of 2 to 2.5 times the recommended IV dose (Table 13-1).¹² The true optimal dose of ET-administered medications is unknown. There is a consensus that IV doses given endotracheally result in subtherapeutic plasma levels.¹³⁻⁴³ The equipotent dose ranges from 3 to 10 times the IV dose.¹³⁻⁴³

Many studies have noted the inadequacy of the currently recommended dose of epinephrine and atropine in cardiopulmonary arrest models.^{28,32,37} The rates of return of spontaneous circulation were significantly greater in the IV medication group than in the ET medication group and in the no therapy group.²⁸

A discussion in the literature has drawn attention to the behavior of epinephrine when given at suboptimal doses. Epinephrine is used in arrest situations for its α -adrenergic effects. However, the β -adrenergic effects predominate when epinephrine is administered

TABLE 13-1 Recommended Endotracheal Medication Doses

Medication	Adults	Pediatrics	Neonates
Atropine	2–2.5 mg	0.03 mg/kg	Unknown (use pediatric dose)
Epinephrine	2–3 mg (1:10,000)	0.1 mg/kg (1:1000) (or 0.1 mL/kg)	0.01–0.03 mg/kg (1:10,000)
Lidocaine	2–3 mg/kg	2–3 mg/kg	Unknown (use pediatric dose)
Naloxone	0.8–2 mg	< 5 years or \leq 20 kg: 0.1 mg/kg \geq 5 years or > 20 kg: 2 mg	0.1 mg/kg
Vasopressin	80 U	Unknown	Unknown

in small doses. This can transiently result in hypotension, decreased coronary perfusion pressure, and a diminished likelihood of return of spontaneous circulation.¹² An early drop in mean arterial blood pressure with prolonged tachycardia in healthy dogs was documented after ET epinephrine at doses of 0.02, 0.035, 0.1, and 0.2 mg/kg.²⁹ Only the 0.3 mg/kg dose was effective in achieving an increase in blood pressure without a transient drop.²⁹ Findings such as these have prompted investigations on pretreatment with beta-blockers (e.g., propranolol) prior to ET epinephrine administration to blunt the early beta-receptor effects.^{30,31} **These studies do question the efficacy of the current recommended ET epinephrine dose and call for higher ET doses.**

Concerns regarding the “depot effect” have kept the current ET medication dose recommendation at 2 to 2.5 times the IV dose. This is to avoid the prolonged side effects in the critical postresuscitation period.⁶ This compromise in dosage leads to uncertainty regarding the effectiveness and reliability of the ET route for medication administration.^{10,32,33}

DILUENT

A primary goal of ET medication administration is to achieve rapid absorption. This goal can be reached with larger volumes of diluent but is tempered by the potentially detrimental effects on pulmonary function.⁵ **The current recommended volumes for the ET route are dilutions to a total volume of 10 mL in adults, 5 mL for children, and 1 mL for neonates.**^{12,27}

Another controversy arises with respect to the type of diluent used. Distilled water and 0.9% saline have both been used for ET medication administration and are currently recommended by the AHA.¹² Water creates a greater osmotic gradient in theory and potentially speeds up medication absorption. Water also leads to a greater disruption of pulmonary surfactant and hinders gas exchange.⁶ The latter was confirmed in nonarrest experiments using dogs.³⁴ It was later disputed using much smaller volumes of instilled medication. These studies found that distilled water provides more rapid and more effective absorption (i.e., higher peak serum medication levels) than 0.9% saline without a physiologically significant drop in PaO₂.^{35,36}

PEDIATRIC CONSIDERATIONS

Obtaining vascular access in children, especially in neonates, can be extremely difficult. This makes the ET medication administration route an important consideration in early resuscitative efforts.³⁸ There are no published pediatric or neonatal studies examining the type or volume of diluent, only consensus recommendations.^{12,27}

A major difference between adults and children in arrest is the absorptive capacity of the lung. The immature lung's surface area is smaller and the diffusion coefficient is larger. There exists the potential for right to left cardiac shunts in children.^{10,39} These conditions greatly affect an already unreliable absorptive process.

The indications, procedure, and complications are much the same in pediatrics as in adults. There are very few published studies focused on ET medication administration in pediatrics. Those involving epinephrine in pediatric arrest agree that it takes 10 times the IV medication dose to achieve appropriate serum epinephrine levels, responses in heart rate, and responses in blood pressure.^{27,39,40} The AHA recommends 2 to 3 times the dose of lidocaine, atropine, or naloxone and 10 times the dose of epinephrine (i.e., 0.1 mg/kg of 1:1000 concentration) when using the ET route.¹²

A retrospective study of neonates who received epinephrine in the delivery room underscores the difficulty of obtaining vascular access.⁴¹ Almost all the neonates received their first dose of epinephrine via the ET route. Almost one-third of the neonates obtained

return of spontaneous circulation, while the rest required additional epinephrine through their IV line once it was established. The authors concluded that the currently recommended ET epinephrine dose of 0.01 to 0.03 mg/kg is ineffective. In the neonatal setting, the AHA states that ET administration of higher dose epinephrine (i.e., 0.05–0.1 mg/kg of 1:10,000 concentration) can be considered, but cautions that the safety and efficacy have not been evaluated.¹²

INDICATIONS

The ET administration of medication is reserved for resuscitations in which vascular access (i.e., IV, intraosseous, or central line) is delayed.¹² The ET route may be more frequently used in certain patient populations traditionally associated with difficult vascular access such as neonates, morbidly obese patients, IV drug abusers, burn patients, and dialysis patients.¹³ **The goal is to increase the probability of successful resuscitation despite a delay in obtaining definitive systemic access. This may soon be outdated with the widespread use of intraosseous access (Chapter 70).**

The ET route is recommended for the administration of lipid-soluble lidocaine, epinephrine, atropine, naloxone, and vasopressin. There are no data to address the ET administration of amiodarone.¹² Other medications that can be administered but are not widely used include flumazenil, diazepam, midazolam, penicillins, sulfonamides, and aminoglycosides.^{14–18}

There is minimal discussion in the literature about the use of ET epinephrine for decompensating and near-fatal asthma. This practice may be considered in moribund patients unresponsive to conventional treatment.^{42–44}

CONTRAINDICATIONS

The absorption of medication given through an ET tube is unpredictable during a cardiopulmonary arrest. The only contraindication to ET medication administration is the establishment of venous access (i.e., IV, intraosseous, or central line).

EQUIPMENT

- ET tube
- Bag-valve-mask
- Medication to be administered
- Diluent, 0.9% normal saline or distilled water
- 10 mL syringe
- 18 gauge needle
- IV adapter lock
- Water-soluble lubricant
- Optional catheters (i.e., suction, feeding, or central venous)

The patient may be intubated with a standard ET tube, an ET tube with a monitoring lumen, or a specialty ET tube with a medication injection port.¹⁹ The EDGAR (Endobronchial Drug and Gas Application during Resuscitation, Rusch, Germany) tube has a separate injection channel that terminates at the tip of the tube (**Figure 13-1A**). This ET tube is currently available in Europe but not in the United States. The Stat-Med ET tube (Hudson RCI, Temecula, CA) has a separate injection port and channel that terminates distal to the inflated cuff (**Figure 13-1B**). Both ET tubes allow the ET administration of medications without interrupting CPR compressions or ventilation. The LITA ET tube (Hudson RCI, Temecula, CA) is a modification of the Stat-Med ET tube (**Figure 13-1C**). It has a separate injection port and channel. The channel has eight openings above the cuff and two below the cuff (**Figure 13-1C**). This ET tube was designed for use with local anesthetic solutions to

FIGURE 13-1. Medication administration ET tubes. **A.** The EDGAR tube. **B.** The Stat-Med tube (Hudson RCI, Temecula, CA). **C.** The LITA tube. (Used with permission from Andrzejowski J, Francis G. The efficacy of lidocaine administered via the LITA tracheal tube in attenuating the extubation response in beta-blocked patients following craniotomy. *Anesthesia* 2002;57:399-401.)

anesthetize the tracheal mucosa. It should not be used to administer resuscitation medications. They will mostly pool above the cuff in the trachea and not get properly absorbed. These specialized ET tubes are rarely available in U.S. Emergency Departments.

Other equipment may be used to administer the medications. A suction, feeding, or central venous catheter may be introduced into the ET tube to administer medications more distally. An IV adapter lock is required on the proximal end of these catheters to allow the syringe to attach to the catheter. There are no formal guidelines regarding proper catheter size; however, it is recommended to use a 16 French (Fr) suction catheter in adults, an 8 Fr feeding catheter in children, and a 5 Fr feeding catheter in neonates.²⁰⁻²²

The administration of drugs through laryngeal mask airways (LMAs; Chapter 26) and Combitubes (Chapter 21) as compared with ET tubes has been studied. Medication instilled via a catheter inserted in an LMA and into the trachea achieved the equivalent blood concentrations as through an ET tube.⁴⁵ It is often difficult to successfully pass a catheter through an LMA and into the trachea.²³ Administration of lidocaine through LMAs was unreliable when compared with ET tubes in nonarrest patients.²³ Subtherapeutic plasma medication levels were noted when comparing lidocaine administration via Combitubes placed in the esophagus versus ET tubes.²⁴

The intubating LMA (ILMA) is a modification of an LMA. It is designed to allow the blind passage of an ET tube through it and into the trachea. Insertion of a catheter through an ILMA was only successful in 92% of attempts.⁴⁶ It also required a mean time of 20 seconds (range of 11 to 44 seconds), which is too long by AHA guidelines to halt CPR.¹²

An interesting device is the LMA MADett or the Endotracheal Tube Mucosal Atomizer Device (Wolfe Tory Medical, Morrisville, NC; **Figure 13-2**). This device allows ET medication administration without stopping compressions and ventilations of CPR and without splash-back. The MADett must be used only with an ET tube size ≥ 7.0 mm inner diameter and a length of at least 28 cm.

TECHNIQUES

PROXIMAL MEDICATION ADMINISTRATION

The simplest method for ET medication administration is direct instillation. Prepare the medication or use a prefilled syringe with a needleless adapter. Use a syringe with an 18 gauge needle to draw up the medication. Remove the 18 gauge needle from the syringe. Draw up sterile water or 0.9% normal saline to dilute the medication to the appropriate volume. Remove the bag-valve device from the ET tube. Briefly interrupt external chest compressions. Inject the

FIGURE 13-2. The MADett. ETT, endotracheal tube. (Courtesy of Teleflex Medical.)

diluted medication into the proximal end of the ET tube. Replace the bag-valve device and manually ventilate five times in quick succession. The forced hyperventilation results in bilateral and distal distribution of the medication.¹³ Resume CPR.

Always remove the needle from the syringe when injecting medication into the ET tube. Some medical personnel may choose to leave the needle attached to the syringe for convenience or to decrease any delays in medication administration. The needle can fall off the syringe and into the ET tube. It will then “ride the tube” and can become a foreign body in the distal trachea or main bronchus. The needle slows down medication injection into the ET tube and delays the resumption of CPR.

PROXIMAL NEEDLE INJECTION INTO THE ENDOTRACHEAL TUBE

An alternative approach is to piercing the proximal end of the ET tube with an 18 gauge needle attached to the medication-filled syringe.²⁵ Care must be taken to assure the needle does not damage the ET cuff inflation tube and that the tip of the needle is completely within the lumen of the ET tube. **Instill the medication during inspiration when the bag is squeezed.** Detach the syringe from the needle. Attach a new medication-filled syringe or refill the used syringe to instill other medications without removing the needle from the ET tube. The remaining hole in the ET tube after the needle is removed results in a negligible air leak that may be closed with a piece of tape.

DISTAL MEDICATION ADMINISTRATION

Medications may be administered deeper through a catheter inserted into the ET tube. This technique minimizes medication adherence to the walls of the ET tube. Prepare the medication and catheter. Draw up the appropriate medication and diluent into a syringe or use a prefilled syringe. Choose the appropriate type and size of catheter. Attach an IV adapter lock to the proximal end of the catheter. The proximal end of the catheter may have to be cut off if it is flared, tapered, or too big for the IV adapter lock to fit.²⁶

Lightly lubricate the catheter with water-soluble lubricant so it will advance easily through the ET tube. Remove the bag-valve device from the ET tube. Briefly interrupt external chest compressions. Insert the catheter (i.e., feeding, central line, or suction) into the ET tube until its tip extends just beyond the distal end of the ET tube by approximately 1 to 2 cm. Attach the medication-filled syringe to the IV catheter lock if using a feeding or suction tube or the Luer lock if using a central venous catheter. Inject the medication into the catheter followed by 5 mL of air to clear the tube of any residual medication. Replace the bag-valve device and manually ventilate five times in quick succession. The forced hyperventilation results in bilateral and distal distribution of the medication.¹³ Resume CPR.

TECHNIQUES TO MINIMIZE COMPRESSION AND VENTILATION INTERRUPTION

The goal of CPR is to minimize interruptions of chest compression and ventilation. This can be accomplished using one of the specialized ET tubes discussed in the equipment section of this chapter. These ET tubes may be placed initially in a patient with a cardiopulmonary arrest or exchanged for a standard ET tube. Prepare the medication. Attach the medication-filled syringe to the injection port of the ET tube. **Inject the medication during inspiration with the bag-valve device.** The diluted drug solution may be followed by the injection of 5 mL of air to clear the ET tube of any residual medication.

An alternative to using these specialty ET tubes is to attach the MADett to a standard ET tube. The MADett is quick, simple, and easy to use (**Figure 13-3**). The patient should already be intubated. Stop ventilations, but not compressions, and remove the bag-valve device from the ET tube. Attach the MADett adapter onto the ET tube (**Figure 13-3A**). Resume ventilations by attaching the bag-valve device to the side port of the adapter. Advance the MADett catheter into the ET tube until the black mark on the catheter lines up with the 26 cm mark on the ET tube (**Figure 13-3B**). Tighten the lock nut on the MADett adapter to hold the catheter in place so it will not be advanced or withdrawn. Attach the medication-filled syringe to the Luer lock. **Inject the medication while ventilating the patient (Figure 13-3C).** Injecting the medication while bagging the patient will allow the atomized medication (**Figure 13-3D**) to penetrate deeply into the respiratory tract.

WHICH IS THE BEST TECHNIQUE?

Mielke et al.²⁶ studied the time involved to perform each technique by Paramedics and Emergency Physicians. These included direct injection into the ET tube, use of a suction catheter, use of a central venous catheter, and use of an EDGAR tube with an injection channel. The direct injection into the ET tube and use of the EDGAR tube were significantly faster than the catheter techniques. A theoretical disadvantage of using a catheter was the instillation of medication unilaterally down one of the main stem bronchi if the catheter was advanced too far down the ET tube. This would thereby decrease the potential absorptive surface by half. This potential negative was offset by larger medication volumes and the application of postinstillation hyperventilation.²⁶

No difference was found in nonarrest patients in the pharmacokinetic response to lidocaine administration with the same three techniques (i.e., direct ET instillation, suction catheter, and EDGAR tube).²⁰ There was no significant difference in serum lidocaine concentration, heart rate, blood pressure, end-tidal PCO₂, and oxygen saturation among the three groups. These findings disputed any previous assertion that using a catheter provided an advantage by instilling medications more peripherally and closer to the absorptive surface. Catheter use led to a significantly longer interruption in ventilation compared to the direct ET instillation group.²⁰

These techniques were evaluated in a porcine model simulating pediatric respiratory arrests.²¹ Radio-labeled epinephrine was instilled through an ET tube, a feeding catheter, and an ET tube with a monitoring lumen. There was no significant difference in hemodynamic response or in the rate of successful resuscitation. The medication adherence to the ET tube was minimal. There was no difference in bilateral pulmonary distribution between the three groups.

ASSESSMENT

Large volumes of fluid in the lung may interfere with oxygen exchange or cause pneumonitis or acute pulmonary edema. Direct the assessments to the resuscitation itself (e.g., chest compression, positive-pressure ventilation, defibrillation). There is no method by which plasma levels of these medications could be obtained rapidly enough to impact clinical care.

AFTERCARE

There is no indication to remove one of the specialty ET tubes if used. These can be left in place and used as one would use a standard ET tube. Place a piece of tape over the hole made by the needle in the ET tube if the needle injection technique was used.

COMPLICATIONS

The main complication of administering medications by the ET route arises from the “depot effect.” Epinephrine, atropine, vasopressin, and lidocaine have been observed to be absorbed in a prolonged fashion, much like a continuous IV infusion. This phenomenon has been attributed to local vasoconstriction (i.e., epinephrine), poor lung perfusion, vascular congestion due to diminished cardiac output, and comorbid conditions (e.g., pulmonary edema, atelectasis, chronic obstructive pulmonary disease) present at the time of the arrest. This sustained drug effect has also been observed in nonarrest patients.⁹ The result of epinephrine administration is prolonged hypertension, malignant arrhythmias, and tachycardia in the postresuscitative period.^{37,45} ET atropine can cause sustained tachycardia.⁶ ET vasopressin can cause sustained bradycardia.¹⁰ A canine study suggested that pretreatment with an IV beta-blocker prior

to ET administration of epinephrine or norepinephrine protected against tachycardia and mildly enhanced the increase in diastolic blood pressure associated with epinephrine.⁴⁷ Another nonarrest canine model suggested that endobronchial rather than ET epinephrine may result in less of the unwanted hemodynamic effects.⁴⁸ We do not have a reliable way to deliver endobronchial medications in the Emergency Department.

A drawback to ET medication administration is the transient impairment of gas exchange. Many studies describe an early reduction in PaO_2 that is directly correlated with the volume of liquid instilled. There is a greater drop in PaO_2 after instilling water than after saline. In nonarrest dogs using large volumes of diluent (2 mL/kg), there was a decrease in PaO_2 to 61% of baseline with distilled water, which was a substantially greater reduction than the decrease in PaO_2 seen with saline.³⁴ In nonarrest humans with instilled volumes of 10 mL through the ET tube,

there was a drop in PaO₂ from 157 to 95 mmHg with saline and from 157 to 103 mmHg with water.³⁵ Hypoxia, to a much greater extent than hypercarbia, has been reported in nonarrest models. Alterations in pulmonary gas exchange in arrest are less well understood. **Adherence to recommended volumes and the use of hyperventilation after instillation has the potential to offset this complication.**

SUMMARY

Despite concerns regarding the efficacy of ET medication administration, this route remains a practical consideration for instances in which vascular access is not yet established for the instillation of resuscitation medications. The ET route will increase the chances of successful return of spontaneous circulation when venous access is delayed. Attempts at vascular access should be continued during the administration of ET medications, and the use of the ET route should be discontinued once access is achieved. Despite its inherent issues, knowledge of the ET medication administration procedure can be lifesaving.

Management of the Difficult Airway

Konstantin Inozemtsev, Gennadiy Voronov, and Ned Nasr

INTRODUCTION

The definition of a difficult airway has remained nebulous despite ongoing international effort due to the complexity and variety of factors constituting this phenomenon. The latest practice guidelines by the American Society of Anesthesiologists (ASA) simply define a difficult airway as an airway that, to a conventionally trained provider, presents a challenge in terms of intubation, ventilation, or both.¹ The reported incidence of a difficult airway in the literature varies. Difficult mask ventilation occurs in approximately 2% of cases, with impossible mask ventilation occurring in 0.15% of cases.^{2,3} Difficult intubation occurs in approximately 5% of cases, with impossible intubation (i.e., failed intubation after multiple attempts at direct laryngoscopy) occurring in 0.3% to 0.5% of cases.⁴ The incidence of both occurring in combination is very low, at less than 2 in 10,000 intubations.²

Failure to control an airway in a timely and reliable manner has been associated with a high degree of morbidity and mortality.^{5,6} Attempts to predict difficulty with airway management and mitigate its impact have met limited success. The ASA proposes 11 anatomic “predictors” of difficulty for intubation and five for mask ventilation.¹ No specific group of these “predictors” has been able to reliably identify problematic airways in advance.⁶⁻⁸ Complex algorithmic models leave a wide “gray area” of uncertainty.⁹ Most difficult airways appear to be unanticipated, even with use of these models.⁷ This leaves the Emergency Physician with a critically important dilemma while under a significant time constraint.

The focus has slowly shifted away from prediction and toward standardized algorithmic approaches. The ASA difficult airway algorithm and the Difficult Airway Society (DAS) algorithms were groundbreaking developments. They were criticized for containing multiple decision points that added complexity without improving outcomes.¹⁰ The favored approach has been extensive training in an institutionally defined, forward-only algorithm for management of the difficult airway.^{10,11} This is often combined with a dedicated team of providers proficient in its use.^{12,13} This works for Anesthesiologists but not for Emergency Physicians working in Emergency Departments with limited backup.

No single method has been endorsed by airway societies. The above approach remains promising due to several key advantages. It offers clear steps in a timely progression to minimize harm and maximize success.^{14,15} An “open-box” approach allows for substitution of locally available tools and techniques within the chain of progression.¹³ Standardized simulation training using such algorithms has demonstrated improved compliance and patient outcomes.¹⁵⁻¹⁷ **Availability of the necessary tools and proficiency in their use are the keys to maximizing success in managing the difficult airway.**^{18,19} However, the tools and proficiency are often lacking in many instances.^{18,19}

ANATOMY OF THE DIFFICULT AIRWAY

A full overview of airway anatomy and its evaluation is contained in the on orotracheal intubation and essential anatomy of the airway (Chapters 9 and 18). **Successfully anticipating the difficult airway may allow the Emergency Physician to select an approach most likely to succeed on the first attempt and to prepare alternative approaches if needed.** Numerous potential predictive factors of difficulty have been identified in the literature. The most common

TABLE 14-1 ASA Predictors of a Difficult Airway

A high, arched palate
A short, thick neck
Limited cervical mobility
Limited mandibular protrusion
Long upper incisors
Mallampati class III or IV
Prominent overbite
Short thyromental distance
Small mouth opening

Source: From reference 1.

predictive factors are those put forth by the ASA and are listed in **Table 14-1**.¹ An acceptable and less cumbersome alternative in the Emergency Department are the LEMON criteria (**Table 14-2**).²⁰ The LEMON criteria provide an effective and rapid way of assessing an airway for potential difficulty.

These risk factors individually have a poor positive predictive value.²¹ **A greater number of suggestive factors increases the likelihood of encountering a difficult airway.** No strict cutoff for the number or combination of predictors has been established. Multiple risk factors should raise suspicion for potential difficulty and the need for flexible endoscopic (Chapter 28) or video-assisted techniques (Chapter 20).

Difficult mask ventilation may result from any factor interfering with proper formation of the face mask seal or excessive resistance to flow of gas. Difficult mask ventilation traditionally has five independent risk factors.³ These are age > 55 years, body mass index > 26 kg/m², presence of a beard that interferes with formation of a tight seal, edentulous state, and history of snoring. The edentulous state has been a commonly cited risk factor because the teeth contribute to the rigid framework that braces facial soft tissue from behind and allows for the creation of a tight seal. More recent work has questioned its contribution to difficult ventilation.³ Edentulous effects may be mitigated by maneuvers (e.g., the jaw-thrust), and limited mandibular protrusion is a more appropriate risk factor for inclusion.³

INDICATIONS

The indications for the application of difficult airway management techniques are the same as those outlined in the orotracheal intubation chapter (Chapter 18). **Difficult airway management techniques are specifically indicated in situations where the initial attempt or technique proves unsuccessful or if difficulty in airway management is anticipated based on the airway examination.**

CONTRAINDICATIONS

The contraindications for application of these techniques and algorithms are listed in the chapters that discuss the specific techniques.

TABLE 14-2 The LEMON Criteria

L — Look externally. Note any craniofacial abnormality and pathology, an edentulous oral cavity, obesity, grossly excessive soft tissue, buck teeth, or a narrow mouth.
E — Evaluate the patient using the 3-3-2 rule. The interincisor distance and hyomental distance should be > 3 fingerbreadths. The thyrohyoid distance should be > 2 fingerbreadths.
M — Mallampati score. Class III (i.e., soft palate and base of the uvula is visible) and IV (i.e., only the hard palate is visible) are nonreassuring findings.
O — Obstruction. Note any pathology within or surrounding the upper airway.
N — Neck mobility. Note if the range of motion is less than 35° at the atlantooccipital joint.

TABLE 14-3 Items Recommended for Inclusion in a Difficult Airway Management Cart or Kit

Airway anesthesia equipment
Antifog solution
Bag-valve devices, various sizes
Bougies or introducers
Devices to confirm proper endotracheal tube placement
Endotracheal tube guides (e.g., semirigid stylets and ventilating tube changer)
Endotracheal tubes, assorted sizes
End-tidal CO ₂ detectors, colorimetric
Face masks, various sizes
Fiberoptic bronchoscope and associated equipment
Flexible fiberoptic intubation equipment
Forceps, various sizes and styles
Lighted stylets
Lubricant
Positive end expiratory pressure valves
Rigid laryngoscope blades of alternate design and size
Scalpels, various sizes
Supraglottic airways (e.g., laryngeal mask airway [LMA] or intubating LMA of assorted sizes)
Surgical airway equipment suitable
Syringes, various sizes
Video laryngoscope

EQUIPMENT

The basic equipment for management of the difficult intubation is similar to that recommended in the orotracheal intubation chapter (Chapter 18). Items recommended for inclusion in a difficult airway management cart or kit are listed in **Table 14-3**.

PATIENT PREPARATION

Preoxygenation or the provision of supplementary oxygen prior to airway manipulation is an important step in airway management. It raises the patient's peripheral capillary oxygen saturation as close to 100% as possible, denitrogenates the blood, and

denitrogenates the residual volume of the lungs.^{22,23} **Use the method of delivery that allows for the highest FiO₂ possible under the circumstances.**²⁴ Patients with an adequate respiratory drive should receive 3 minutes of preoxygenation or take eight vital capacity breaths with maximal exhalation and inhalation. Noninvasive positive-pressure ventilation (e.g., continuous positive airway pressure [CPAP]) via mask connected to a bag-mask device with a positive end expiratory pressure valve may be superior for those unable to achieve acceptable saturations (e.g., > 93% to 95%) with standard techniques.²⁴ Positioning the patient in a head-elevated position, especially for the obese, may be beneficial compared to laying them supine during preoxygenation. The provision of apneic oxygenation with maximal flow of oxygen delivered via nasal cannula with or without nasopharyngeal airway insertion may further extend the duration of safe apnea.²⁴ These modalities may be combined in high-risk patients.

The remainder of the preparation for airway management is similar to that described in the orotracheal intubation chapter (Chapter 18). Device-specific preparation is described in the appropriate chapter. The Emergency Physician should have the equipment necessary for rapid and sequential progression from one technique to the next in case of failure to successfully control the airway (**Figures 14-1, 14-2, 14-3, and 14-4**).²³

Difficult airway carts arranged in a sequential manner that reflects the order in which they would be used have been recommended by the ASA and the DAS. A designated kit or cart should be used given that equipment availability is a known impediment in airway management.²⁵

The recommended medications are noted in Chapters 12, 16, 18, and 28. Propofol provides superior conditions for airway management and suppresses laryngeal reflexes. Neuromuscular blocking agents can facilitate ventilation, abolish laryngeal reflexes, and increase tissue compliance. Succinylcholine at 1.0 to 1.5 mg/kg intravenously is commonly used in rapid sequence intubation.²⁶ Rocuronium may be preferable in patients at high risk of desaturation as succinylcholine appears to decrease the time to desaturation due to fasciculations, increasing oxygen utilization.²⁴ The essential components of awake airway management include psychological

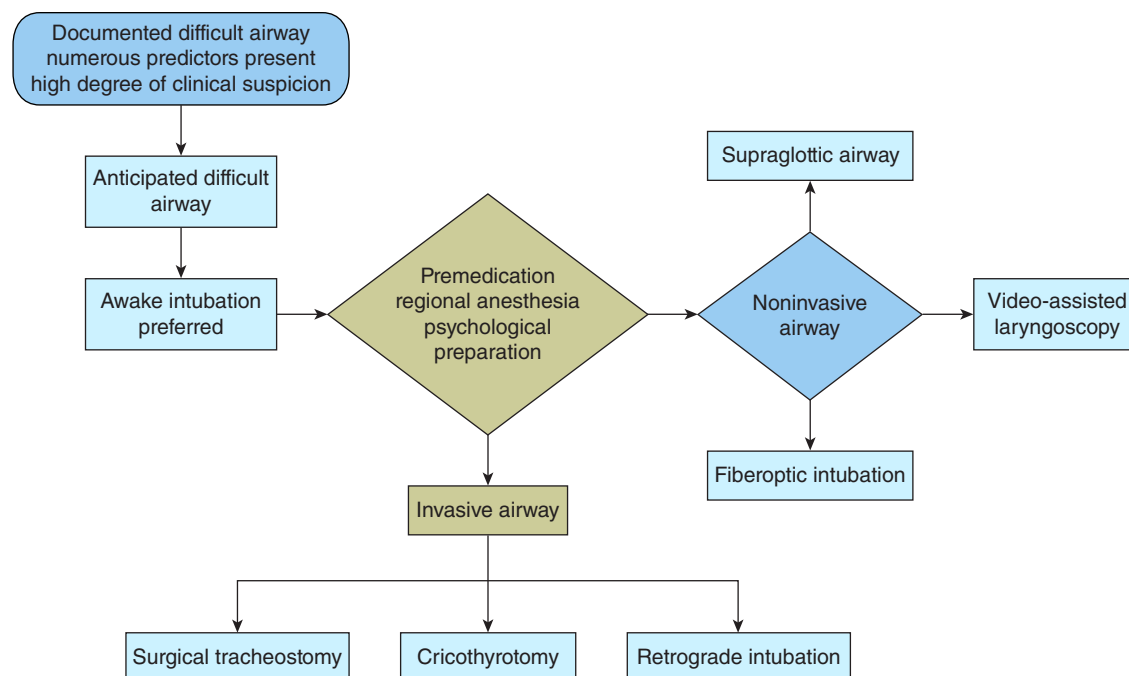

FIGURE 14-1. Basic algorithm for progression through the anticipated difficult airway.

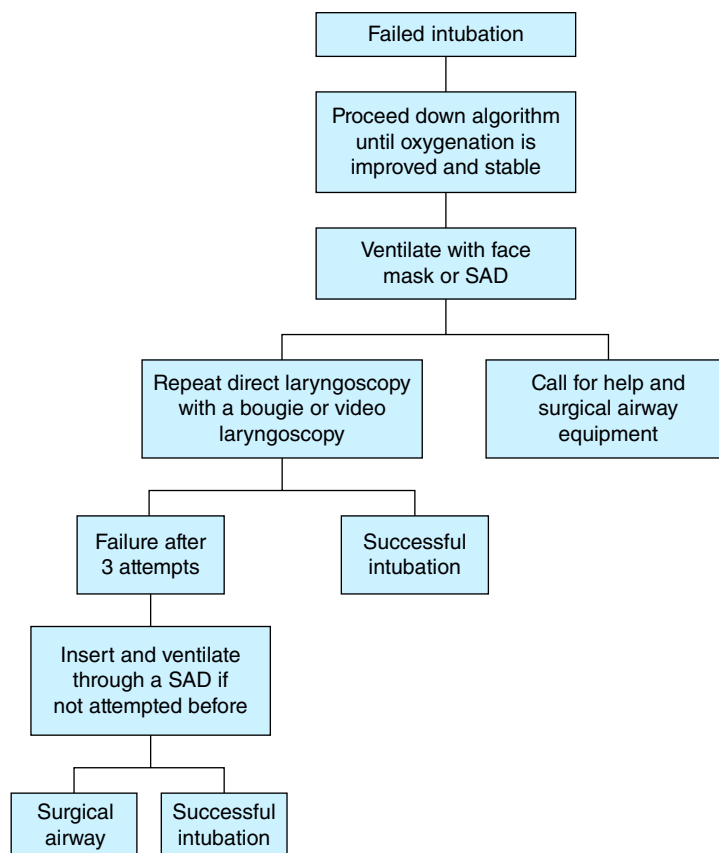

FIGURE 14-2. Example algorithm for progression through an unanticipated difficult airway. SAD, supraglottic airway device.

preparation of the patient, the use of antisialagogues (e.g., glycopyrrolate), provision of anxiolysis and sedation (e.g., midazolam and dexmedetomidine), and topical and/or regional anesthesia with lidocaine. This applies to fiberoptic bronchoscopic intubation, video laryngoscopy intubation, supraglottic airway placement, and surgical airway placement.

OPTIMAL PATIENT POSITIONING

The default position during direct laryngoscopy is the “sniffing position.” It is achieved by 35° cervical flexion and maximal extension of the atlantooccipital joint.²⁶ This position allows for theoretical alignment of the oral, laryngeal, and pharyngeal axes for optimal visualization of the vocal cords. It has become the standard of practice in direct laryngoscopy since its detailed description in 1944.²⁷ Some recent efforts have called the scientific basis and superiority of this technique into question.^{28,29} The sniffing position reliably reduces intubation difficulty.³⁰ The sniffing position is an appropriate initial choice for patients with limited cervical mobility and the obese.^{28,31} Simple head extension may be sufficient to obtain a satisfactory view for the average-sized patient.²⁸

The increased anteroposterior diameter of the chest in the obese population makes the standard sniffing position virtually impossible to attain without anterior displacement of the shoulders. The “ramped” position is achieved by using a specialized wedge-shaped device or a stack of blankets to elevate the upper torso and align the sternal notch with the external auditory meatus in the horizontal plane. **The ramped position has been demonstrated to improve laryngeal views in obese patients and should be routinely used.**³²⁻³⁵ **Consider the ramped position for all obese patients undergoing direct laryngoscopy given that obesity is associated with difficult mask ventilation, faster desaturation, lower tolerance for apnea,**

an increased risk of difficult intubation, and difficult emergency tracheotomy.^{3,23,36-41} Further description of the management of the obese airway is contained in Chapter 15.

TECHNIQUES

The Emergency Physician may default to an approach most likely to successfully navigate the anatomic and physiologic complexities if a difficult airway is accurately anticipated and encountered under controlled conditions. A simple outline for approaching the anticipated difficult airway is presented below.

THE ANTICIPATED DIFFICULT AIRWAY

NONINVASIVE AIRWAY ACCESS

It is important to realize that there are numerous options for management of the anticipated difficult airway (**Figure 14-1**). Selection of the technique most likely to be successful based on the Emergency Physician’s comfort and familiarity and the patient characteristics is appropriate if adequate time is available. Many of the techniques can be performed while the patient is awake given the proper preparation for the anticipated difficult airway. Awake intubation allows the Emergency Physician to maintain spontaneous oxygenation and ventilation, minimize the hemodynamic impact of sedating medications, preserve normal muscle tone, and navigate the anatomic architecture of the upper airway, while allowing the patient to maintain protective airway reflexes.⁴² Noninvasive and invasive techniques may be appropriate for a complicated airway. Fiberoptic intubation via flexible bronchoscopy (Chapter 28) is often the approach of choice and may be considered the gold standard for expected difficult airway management.⁴³ Fiberoptic intubation may

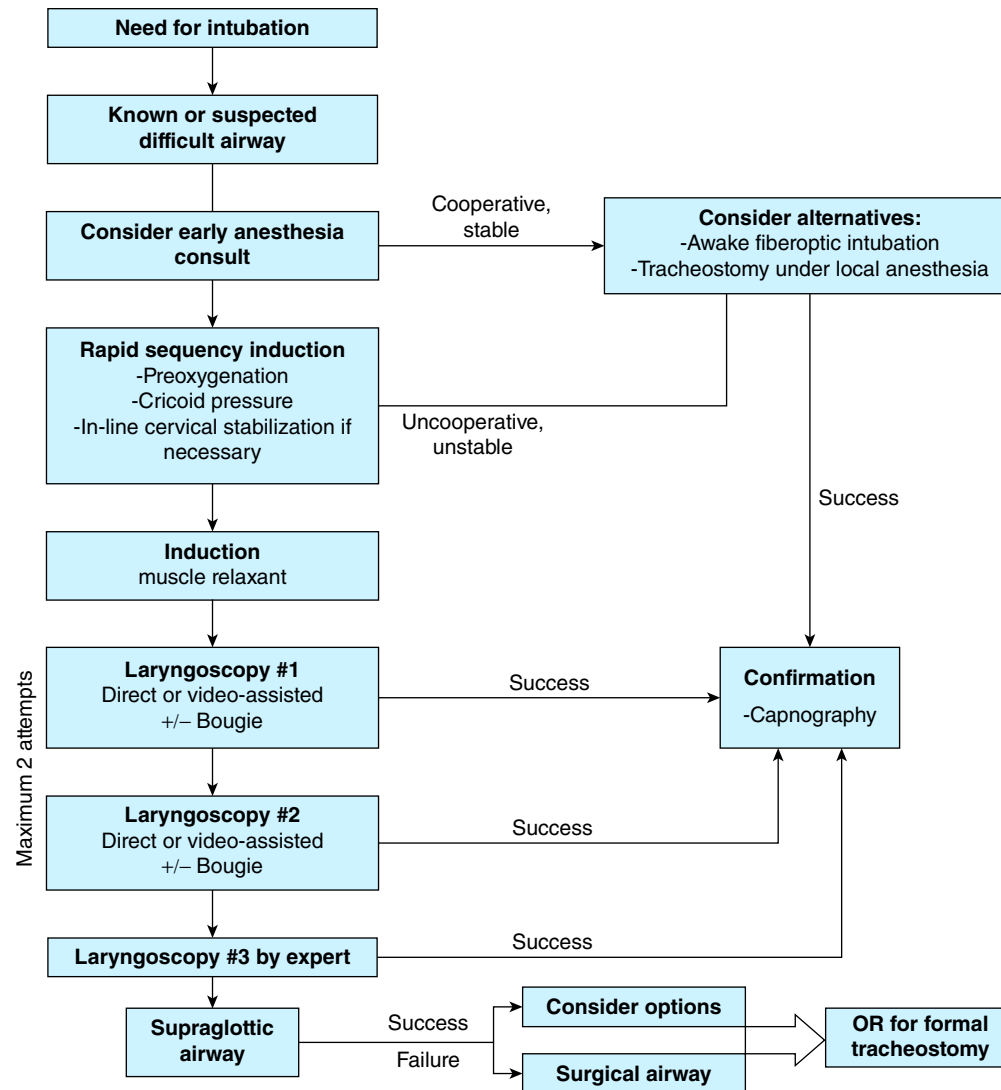

FIGURE 14-3. An institutional difficult airway algorithm. OR, Operating Room.

not always be a practical or readily available technique because it requires a dedicated tower to provide an external light source and monitor. Alternatives are using the single-use aScope (Ambu, Ballerup, Denmark) or rigid bronchoscopy, which permits simultaneous ventilation.

Video-assisted orotracheal intubation devices (e.g., GlideScope, Bonfils, Shikani, and Airtraq) represent a simpler alternative to fiberoptic bronchoscopy that circumvents the limitations of direct laryngoscopy (Chapters 20 and 21). These may be channeled (i.e., with the device and endotracheal tube moving as a single unit) or nonchanneled (i.e., with the endotracheal tube directed with the assistance of a stylet). Video laryngoscopes usually have self-contained light emitters, dedicated monitors, and power sources; require less dedicated equipment and space than fiberoptic bronchoscopes; and are easy to incorporate into clinical practice.⁴⁴ **Current literature suggests their usefulness, although not their superiority, in difficult airway management.**^{43,45} A wide variety of video laryngoscopes are available.

The supraglottic airway device (SAD) is useful in the anticipated difficult airway (Chapters 25 and 26). A SAD may be used for the awake and sedated patient. The intubating laryngeal mask airway (e.g., ILMA or LMA-Fastrach) is a type of SAD that allows for ventilation and oxygenation while serving as a conduit for passage of

an endotracheal tube.^{46,47} The ILMA has become an important part of difficult airway management due to its high success rate in the adult and pediatric population.^{48,49} Numerous alternatives to the ILMA exist (e.g., LMA CTrach with built-in fiberoptic imaging and the ProSeal, which supports higher seal pressures and provides access to the esophagus).⁴³ **SADs may be used when fiberoptic intubation fails.**⁵⁰ Fiberoptic intubation and ILMA demonstrate a high success rate and can be complementary to each other.⁵¹ They can be used in conjunction or sequentially if the first attempt is unsuccessful.

INVASIVE AIRWAY ACCESS

Invasive airway placement may be appropriate. Retrograde intubation involves cannulation of the trachea via the cricothyroid membrane and the insertion of a guidewire to serve as a conduit for intubation (Chapter 30). The technique can be performed under local anesthesia. It negates the need for visualization and navigation of the laryngeal inlet. It can be very useful in overcoming significant anomalies and distortions in airway anatomy, circumventing excessive blood and secretions, and as a rescue technique after other techniques (e.g., direct laryngoscopy, SADs, and flexible bronchoscopy) have failed.⁵²⁻⁵⁴ Surgical airways (e.g., cricothyrotomy or

FIGURE 14-4. An example of a difficult airway cart. Note the drawers are clearly labeled.

tracheostomy) may be performed if clinically warranted, if there is availability of the necessary equipment, and if a trained Emergency Physician is present.⁵⁴

THE UNANTICIPATED DIFFICULT AIRWAY

NONINVASIVE AIRWAY ACCESS

Most encountered difficult airways are unanticipated and often encountered under emergent conditions.⁷ The emergent nature of airway management may preclude elaborate evaluation, planning, and utilization of unfamiliar and labor-intensive techniques. Numerous algorithms and approaches exist in literature. They commonly begin with direct laryngoscopy followed by SAD insertion and terminate in invasive airway placement (Figure 14-2). **Memo- rization of a specific sequence is potentially helpful but not as important as understanding the logic behind it. The focus is on reestablishment and optimization of ventilation by rapid progression through available techniques from the least invasive to the most invasive.**

DIRECT AND VIDEO LARYNGOSCOPY

The initial approach to orotracheal intubation is rapid sequence intubation (RSI) via direct laryngoscopy (Chapter 16). Conventional direct laryngoscopy may be replaced with video-assisted laryngoscopy (Chapter 20).⁵⁵⁻⁵⁹ Limited evidence suggests it may offer superior views and higher success rates in less experienced providers.^{45,60} Video laryngoscopy may be the most successful rescue technique for failed laryngoscopy.⁶¹

The ASA guidelines no longer include a strict numerical attempt value in their definition of difficult intubation. Multiple attempts (e.g., three or more) at vocal cord visualization via direct laryn- goscopy have been associated with a significant increase in airway

adverse events and hemodynamic compromise (e.g., aspiration, hypoxemia, and cardiac arrest).⁴⁶ **It is prudent to limit the num- ber of attempts at direct laryngoscopy, with timely progression to alternative modes of airway management and a call for help should the first one or two attempts fail.** The DAS allows for a fourth attempt by an experienced provider before proceeding to alternative methods of securing the airway.

LARYNGOSCOPY IMPROVEMENTS AND ADJUNCTS

Manual external manipulation of the larynx by the Emergency Physician or an assistant may improve the laryngoscopic view. The “BURP” maneuver (i.e., external application of *backward upward rightward* pressure to the larynx with the right hand) is a well-described manipulation known to be helpful but may worsen the view in some cases.⁴² Cricoid pressure (i.e., Sellick’s maneuver), which involves the application of pressure to the cricoid ring to occlude the upper esophagus and prevent aspiration, may interfere with vocal cord visualization.²⁶ The process is often one of trial and error due to the anatomic variations and dynamic nature of airway management.

INTRODUCERS, BOUGIES, AND STYLETS

Stylets are malleable rods that permit shaping of the endotracheal tube. They allow the user to direct the endotracheal tube for greater placement precision but carry the risk of airway trauma. These should be molded to have the same 30° to 40° angle at the tip with the endotracheal tube extending past the distal end of the stylet.⁴³

Introducers are rigid or semi-rigid rods inserted into the airway, and then an endotracheal tube is passed over them (Chapter 22).⁶² Introducers have an angled tip and can be bent to some degree, and an endotracheal tube can be passed over them with ease. The Eschmann endotracheal tube introducer (frequently referred to as a “bougie”) is a reusable, 60 cm long introducer. The Eschmann flexed tip permits obstacle avoidance and lifting of the epiglottis and provides tactile feedback in the form of “clicking” as it passes over the tracheal rings to confirm its proper location.⁴³ It has a high success rate and low complication rate. The Frova intubating introducer is a single-use alternative of similar design. The Frova is improved by the presence of a hollow lumen that permits ventilation and CO₂ detection while having a similar success rate to that of the Eschmann introducer.^{63,64} Light wands (i.e., Trachlight) can be used to intubate and/or confirm endotracheal tube placement by transillumination of the anterior neck (Chapter 24).⁶⁵

ALTERNATIVES AND RESCUE TECHNIQUES FOR FAILED INTUBATION

Measures to restore ventilation and oxygenation must be imple- mented if initial attempts at intubation are unsuccessful. Use temporizing measures (e.g., mask ventilation) whenever possible.

SUPRAGLOTTIC AIRWAY DEVICE (SAD)

Consider the insertion of a SAD. Have several SADs of varying sizes immediately available in the setting of an unrecognized dif- ficult airway, when the vocal cords cannot easily be visualized, or the airway cannot be intubated.^{1,23} **The SAD serves an essential role in difficult airway management for adult and pediatric patients.** The SAD and is typically the “plan B” that follows direct laryngoscopy due to its unique advantages and high success rates of 95% to 99%.^{1,23,66} It may be inserted swiftly and blindly to create a low-pressure seal over the laryngeal inlet that permits effective

ventilation when the vocal cords are impossible to visualize. The SAD bypasses soft tissues that may be obstructing the view and limits the risks associated with direct laryngoscopy.²⁶ The SAD tube may serve as a conduit for flexible bronchoscopic intubation, a bougie, or an intubating stylet.⁶⁶

SADs have drawbacks inherent to their design. They are unable to protect the airway from aspiration and laryngospasm. They cannot generate the high pressures necessary to overcome poorly compliant airways. They carry a risk of dislodgement and gastric insufflation, although later models have features that minimize this risk.²⁶

A maximum of three attempts are allowed to successfully insert the SAD and ventilate the patient per the DAS guidelines. Make two attempts with a preferred second-generation SAD (e.g., LMA Supreme or Proseal LMA) and one attempt with an alternative; further attempts contribute to increased risk without demonstrating a clear improvement in intubation success.²³ Cricoid pressure may interfere with SAD placement.²³ **Do not use cricoid pressure after direct laryngoscopy has proven unsuccessful.**²³

EMERGENCY INVASIVE AIRWAYS

Progression to establishing a surgical airway is warranted in the rare event of a “cannot intubate, cannot ventilate” (CICV) scenario. **Do not delay the progression to an invasive airway.** Options include the percutaneous transtracheal jet ventilation (Chapter 31), cricothyroidotomy (Chapter 32), and tracheostomy (Chapter 33). Reserve these techniques for when all other techniques have been exhausted due to the invasiveness of these procedures and the associated risks (e.g., barotrauma, subcutaneous and mediastinal emphysema, hemorrhage, perforation, nerve injury, and infection).²⁶ **Emergency Physicians should be adequately trained in these techniques to mitigate their complications and high rate of failure.**⁶⁷

PEDIATRIC CONSIDERATIONS

A higher minute oxygen consumption and a smaller respiratory reserve result in a low tolerance for apnea, with hypoxemia and bradycardia rapidly following the cessation of breathing in the pediatric patient.⁶⁸ The pediatric difficult airway is complicated by anatomic and physiologic differences from its adult counterpart. The approach to the difficult airway remains largely unchanged. Awake intubation remains a possible and adequate choice if the patient is cooperative.⁶⁹ Direct laryngoscopy is best achieved with a Miller blade. The curved Macintosh blade may not adequately displace the tongue. Video laryngoscopy using pediatric blades is an acceptable approach.⁷⁰ SADs have demonstrated excellent success rates in children with difficult airways, and success rates approach 96%.⁴⁸ Invasive techniques remain a possibility but present a considerable challenge given the smaller airway structures and higher risk for injury.⁶⁹

ASSESSMENT

Successful placement of an airway device must be confirmed (Chapter 19). Visual confirmation of endotracheal tube passage through the vocal cords, continuous capnography, bilateral chest expansion, and auscultation for presence of breath sounds can be used to confirm endotracheal intubation. Waveform analysis of continuous capnography with appropriate and stable end-tidal CO₂ values remains the gold standard. **Absence of exhaled CO₂ detection signifies malposition of the airway device or airway obstruction.**²³

AFTERCARE

The device needs to be secured so control of the airway is not lost. The specific aftercare depends of the technique used. See the appropriate chapter that discusses the technique.

COMPLICATIONS

Difficult airways contribute to a large proportion of airway-related adverse events. There are numerous complications associated with the difficult airway (e.g., aspiration pneumonitis, brain damage, death, emotional distress, Intensive Care Unit admission, need for a surgical airway, and nerve injury).^{5,67} Device-specific complications are discussed in the appropriate chapter with the technique.

SUMMARY

The keys to the management of a difficult airway include early recognition, selection of a technique most likely to succeed based on patient characteristics and Emergency Physician training, and a clearly delineated plan of progression if the initial intubation plan fails. Training in management of difficult airways with timely initiation and progression of alternate/rescue techniques is paramount. Creation of a standardized difficult airway kit or cart and presence of a well-trained Emergency Physician may further reduce the risks and improve outcomes associated with this challenging phenomenon.¹³

Obese Airway

Charles Boland, Piotr Al-Jindi, and Ned F. Nasr

INTRODUCTION

Airway control is one of the most critical actions taken during an emergency response. It is not always straightforward and can present with many variations, creating challenges for the Emergency Physician. Many factors contribute to a difficult airway, with obesity becoming one of the most prevalent in the United States.¹ The negative effects of obesity are seen in nearly every organ system through anatomic, physiologic, and metabolic changes. The Emergency Physician must take these changes into account when attempting an endotracheal intubation in an obese patient, including a thorough understanding of the anatomy, physiology, equipment necessary, and complications. This chapter will aid in providing a better understanding of what many consider the most daunting challenge to an Emergency Physician.

ANATOMY AND PATHOPHYSIOLOGY

We will discuss the important variances seen in obesity and how they affect management. There is an overall increase in fat deposition within soft tissue structures in the oropharynx in a morbidly obese patient. These fat depositions can lead to enlarged lateral pharyngeal walls and a soft palate, a decrease in the caliber of the upper airway, and an increase risk of airway collapse.² **Neck circumference > 40 cm, a short neck, decreased mobility of the cervical spine, and a Mallampati class of III or IV are the best predictors of difficult ventilation with a mask and difficult intubation.**³⁻⁶ A study performed by Stanford University showed that neck circumferences of 40 cm and 60 cm were associated with 5% and 35% probabilities of difficult intubation, respectively.⁷ A large neck circumference does not indicate where fat is distributed along specific areas of the anterior neck. More fat is deposited around collapsible pharyngeal segments in patients with obstructive sleep apnea (OSA) syndrome (**Table 15-1**).⁸⁻¹¹ Obesity is a clear risk factor for developing OSA.¹²⁻¹⁴ Further investigation is needed to clarify the conflicting evidence associating OSA with difficult intubations. **Positioning plays a key role in alleviating the difficulties provided by anatomic variations and soft tissue distributions.**¹

TABLE 15-1 The STOP-BANG Screening Questions for OSA

Snoring	Do you snore loudly? Louder than talking? Can it be heard through a closed door?
Tired	How often do you feel fatigued, sleepy, or tired during the day? Do you fall asleep in the day?
Observed	Has someone observed you to choke, gasp, or stop breathing during sleep?
Blood Pressure	Do you have high blood pressure? Are you treated for high blood pressure?
BMI	Is the BMI greater than 35 kg/m ² ?
Age	Is the age greater than 50 years?
Neck	Is the circumference around the level of the laryngeal prominence greater than 43 cm (17 inches) for a male or greater than 41 cm (16 inches) for a female?
Gender	Is the patient a male?

1 point is given for each positive answer.

A score ≥ 5 signifies a risk for OSA.

Source: Modified from references 10 and 11.

The physiologic differences found in obesity offer many considerations for the Emergency Physician when approaching the airway. Obesity increases the risk of other medical problems (e.g., hypertension, type 2 diabetes, OSA, and atherosclerosis). These can negatively affect the patient's health. These diseases require the Emergency Physician to alter the approach, preparation, and execution of tracheal intubation.¹⁵

Respiratory changes in obesity occur due to physical impairment of the chest wall. The increased body mass restricts diaphragmatic excursion, leads to hypoventilation, and decreases respiratory compliance.¹⁶ Increased fatty tissue causes elevated metabolic requirements and increased oxygen consumption.¹⁷ This results in the obese patient having an increased respiratory rate. The most important lung volumes for intubating, the functional residual capacity and the expiratory reserve volume, are decreased in obesity. These changes lead to increased atelectasis, worsening ventilation-perfusion mismatch, and increased right-to-left shunt.¹⁸ The supine position and induction of anesthesia lead to these changes. Obesity worsens the effect to a much greater degree.¹⁹ Obese patients may need a higher tidal volume for respirations to move the chest wall.²⁰ **These physiologic differences can drastically shorten the time to desaturation once the patient is apneic after induction.**^{12,21} This further emphasizes the importance of preparation, positioning, and preoxygenation.

EQUIPMENT

- Equipment for orotracheal intubation (Chapter 18)
- Rubber head strap
- Equipment for noninvasive positive-pressure ventilation (NIPPV)
- Folded clean sheets to stack under the patient for positioning
- Laryngeal mask airways, various sizes (Chapter 26)
- Endotracheal tube introducer or bougie (Chapter 22)
- Video laryngoscope (Chapter 20)
- Fiberoptic bronchoscope (Chapter 28)
- Fiberoptic intubating oral airway, various sizes
- Cricothyroidotomy supplies (Chapter 32)
- Additional medications (**Table 15-2**)

Many institutions have airway bags or carts with standard equipment. The above listed equipment is most likely in the difficult airway cart.

TABLE 15-2 Weight-Based Dosing Recommendations for Commonly Used Medications

Medication	Induction dosing by weight	Induction dose (IV)
Cisatracurium	IBW	0.1 mg/kg
Etomidate	IBW	0.2–0.3 mg/kg
Fentanyl	LBW	1.5–3.0 mcg/kg
Ketamine	IBW	1.0–2.0 mg/kg
Propofol	LBW	1.0–2.5 mg/kg
Remifentanyl	LBW	1.0–3.0 mcg/kg
Rocuronium	IBW	0.6–1.2 mg/kg
Succinylcholine	TBW	1.0–1.5 mg/kg
Sugammadex	IBW	16 mg/kg
Thiopental	LBW	3.0–5.0 mg/kg
Vecuronium	IBW	0.1 mg/kg

Abbreviations: IBW, ideal body weight; IV, intravenous; LBW, lean body weight; TBW, total body weight.

LARYNGEAL MASK AIRWAYS

The laryngeal mask airway (LMA) is a generic term used to describe many devices. The LMA is a device used as an alternative to mask ventilation and to endotracheally intubate. LMAs are an integral part of the most current difficult airway algorithm. They are devices that can be inserted into the pharynx to allow for ventilation, oxygenation, and a conduit for endotracheal intubation. They can be used as a primary airway or a backup airway.

The LMA consists of a hollow tube attached to a mask-like cuff designed to rest in the hypopharynx with the opening facing the glottis and the tip in the esophageal opening. LMAs come in different shapes, constructions, and sizes with unique features for various functions. The authors recommend managing an emergent difficult airway with a second-generation LMA designed with additional ports for orogastric tube and blind endotracheal tube insertion. Examples include the i-Gel (Chapter 25), Air-Q (Chapter 26), and LMA Fastrach (Chapter 26). Each type comes in different sizes, with some having half sizes. Each manufacturer recommends sizes based on patient weight. Predicting a proper fit can be difficult. Have available one to two sizes larger and smaller than predicted for the patient. Intubating LMAs allow an endotracheal tube through the ventilation port, the glottis, and into the trachea. The size of the endotracheal tube able to pass through the LMA varies with the size of the LMA. The Emergency Physician must be sure to check the manufacturer's recommendations.

ENDOTRACHEAL TUBE INTRODUCER OR BOUGIE

The endotracheal tube introducer is commonly referred to as a bougie (Chapter 22). **Introducers are underused devices that can be invaluable during a difficult intubation.** This device is a long, flexible, nonmalleable stylet with the distal tip fixed at a 30° angle. The bougie is used when encountering an anterior airway, a grade III Cormack-Lehane view, or a grade IV Cormack-Lehane view on direct laryngoscopy. It can be difficult to pass an endotracheal tube regardless of how much curvature is placed with a regular stylet. The 30° curve at the end of a bougie allows for anterior direction and passage through the vocal cords, even when they cannot be seen. The tracheal rings can be felt as the curved end of the bougie passes over them. An bougie can be used as a conduit through the vocal cords to pass an endotracheal tube over it and into the trachea. **Have a bougie readily available when intubating an obese patient. The threshold for its use should be low to avoid unnecessary pharyngeal and laryngeal trauma caused by multiple attempts with a regular endotracheal tube and stylet.**

VIDEO LARYNGOSCOPE

Video laryngoscopes (Chapter 20) consistently achieve a better view of the glottis when used in difficult airways compared with direct laryngoscopy and improve intubating conditions.^{12,22-26} A small video camera is at the end of a fiberoptic handle and wired to a video screen to provide a wide-angle view of the entire glottic aperture. A specialized stylet with a fixed anterior curvature is typically used to pass the endotracheal tube. Some video laryngoscopes mimic a Macintosh laryngoscope blade, which the Emergency Physician is already comfortable using. Pass a video laryngoscope blade different from the direct laryngoscope by inserting it in the midline.

Insert the video laryngoscope and endotracheal tube until the cuff is seen at or just past the vocal cords. A second provider or assistant should carefully remove the stylet while the Emergency Physician firmly holds the endotracheal tube in place. As the stylet is removed, the endotracheal tube is carefully rotated in a clockwise fashion

under continuous video monitoring until it passes completely into the trachea. The blade and handle are removed once the endotracheal tube is seen going into the trachea on the video laryngoscope. **It is of utmost importance to not advance the endotracheal tube balloon beyond the vocal cords with the rigid stylet in place to prevent tracheal injury.**

PATIENT PREPARATION

Preparation is of the utmost importance due to the frequently encountered difficulties. Take a brief history if the patient is conscious and able to communicate. Information includes past medical history, current medications, previous surgeries, allergies, last food or drink intake, illicit drug use, and a history of difficult intubations.¹² Perform a brief physical examination, and focus on the airway, cardiac system, pulmonary system, and neurologic status.

The airway examination is one of the most important aspects of the patient assessment. The highest predictor of a difficult intubation is a history of a difficult intubation. Important features to note are a thick or short neck, the thyromental distance, presence of facial hair, and the presence of cervical collars.²⁷ These features are predictive of difficult ventilation. Assess and estimate mouth opening. An opening less than 6 cm or three finger breadths is considered limited and can predict difficulty with direct laryngoscopy. Assess the length and health of the patient's dentition. Teeth that are very long, cracked, missing, capped, or loose should be noted prior to instrumentation of the airway. Note the presence of dentures and remove them prior to direct laryngoscopy. Assess the oral and pharyngeal structures and describe the view using the Mallampati class. This is estimated with the patient's mouth open, tongue protruding, and without phonation. Thyromental distance is estimated using finger breadths. A distance less than 6 cm is considered limited. This is the area that accommodates the tongue during direct laryngoscopy. Neck mobility is assessed with the patient sitting upright and moving their head from full flexion to full extension. Limited range of motion predicts difficulty aligning the external auditory meatus with the sternal notch and achieving an unobstructed view of the glottis during direct laryngoscopy.²⁸ This motion is not assessed in the patient wearing a cervical collar.

POSITIONING

Positioning is a key element of preparation that is frequently overlooked and underappreciated.¹² The supine position is disadvantageous for respiratory mechanics and oxygenation. **A ramped or head-elevated position improves respiratory mechanics and improves the glottic view.**²⁹⁻³² The head elevated 25° improved the glottic view by 50% when compared to a flat supine position.³³ The ramp position maintained or improved the view in 100% of patients with a body mass index (BMI) > 45 kg/m².³⁴ The ramped position can be achieved by two common methods that have been shown to be equally effective.³⁵ The first method uses folded sheets placed under the patient's upper body with an increasing elevation (Figure 15-1). The second is to elevate the head of the bed where the goal is to align the patient's external auditory meatus with the sternal notch (Figure 15-2). Use reverse Trendelenburg if the patient cannot be placed in the ramped position. **This position uses gravity to move the abdominal contents down and allow the diaphragm to fully expand.**

PREOXYGENATION

Equally as important as positioning is adequate preoxygenation.³⁶ The most effective technique for preoxygenation is achieved with the patient in the upright or sitting position and spontaneously

FIGURE 15-1. The patient in the ramped position using folded sheets.

breathing normal tidal volumes for 3 to 5 minutes.³⁷ The average time to saturations of 90% was increased by 1 minute over the supine position with the patient in the full upright position.³⁸ A possible approach could be to preoxygenate the patient in the sitting position and lower the gurney to an elevated position during intubation. This allows for maximum apneic time benefiting both the patient and Emergency Physician. A small randomized trial proved that providing the patient with 5 L of oxygen via nasal cannula during intubation added 90 seconds to the apneic period.³⁸

MEDICATION DOSING

Obese patients have alterations in the pharmacokinetics and pharmacodynamics of medications. Obese patients have increased total body weight, with an increase in both fatty tissue weight and lean body weight. These changes lead to an increase in cardiac output, tidal volume, and glomerular filtration rate (GFR). An increase in fatty tissue causes more volume of distribution for lipophilic drugs (e.g., benzodiazepines and fentanyl). Base the dosing of lipophilic medications on total body weight or ideal body weight (Tables 15-2 and 15-3).³⁹ Obese patients often receive the incorrect dosage.³⁹

FIGURE 15-2. The patient in the ramped position using elevation of the head of the bed.

HOWLAND LOCK

Consider using a Howland Lock (SunMed, Grand Rapids, MI) to intubate the obese patient. This piece of equipment attaches between the laryngoscope handle and blade (Figure 15-3). It can prevent the angle of an obese patient's chest from interfering with intubation. It reduces the chance of levering the laryngoscope on the patient's teeth and causing any damage. It was developed for the difficult airway and helps if the patient has an anterior larynx, decreased jaw mobility, facial contractures, protruding teeth, a receding chin, or a short neck, or is obese.

TECHNIQUE

RAPID SEQUENCE INDUCTION

Proper execution of an obese intubation with minimal or no complications almost entirely depends upon excellent patient and provider preparation. The Emergency Physician often has ample time to complete the task and all resources available to manage unexpected complications, thus providing a less stressful atmosphere to work. The head of the bed should be 2 to 3 feet from the wall to allow maneuvering room. Place the patient all the way to the head of the bed in a head-elevated or ramped position (Figures 15-1 and 15-2). Consider the application of a nasal cannula to provide oxygen during the rapid sequence intubation to prevent the patient from desaturating. Adjust the height of the bed so that the forehead of the patient is at the level of the Emergency Physician's umbilicus. Respiratory personnel should be to the right of the Emergency Physician and ready to assist. Position an assistant of equal or greater experience (i.e., another Emergency Physician) and able to assist in any way needed to the left of the Emergency Physician who is intubating. This person can attempt intubation if difficulty is encountered. Prepare the endotracheal tube. There is no correlation of a larger BMI to a larger airway.⁴⁰ The obese patient often has a decreased tracheal width.⁴⁰ **Avoid larger endotracheal tubes due to greater BMI. Be prepared to perform a cricothyrotomy.**

Use a rapid sequence intubation technique (Chapter 16). The obese airway is often a difficult airway. The oral intake status is often unknown in the Emergency Department. The apneic time is decreased in obese patients, so securing the airway quickly is vital. Adequate preoxygenation for intubation is determined by an expiratory O₂ concentration of greater than 80%. A normal tidal volume of breathing for 3 minutes on 100% FiO₂ in at least a 45° head-elevated position is sufficient if real-time analysis is not immediately available. Hold the face mask gently against the patient's face with a hand or rubber face mask strap to prevent leaks. Prepare the endotracheal tube and place it within reach. Check that the laryngoscope is working and place it next to the patient's head. **The "best" blade is whichever blade the Emergency Physician has the most experience with and is most confident using.** Have the Nurse prepare and draw up the medications used in the intubation and immediately afterward.

Preoxygenate the patient and proceed. Instruct an assistant to place light pressure over the cricoid cartilage. Increase the cricoid pressure when the patient is asleep. This is done as a measure to prevent regurgitation and aspiration of gastric contents. Administer a small dose of a fast-acting opioid (e.g., 50 mcg fentanyl) due to its respiratory depressing side effects. Propofol is often used due to its fast onset and offset. Propofol can cause hypotension. Etomidate can be used as an alternate sedative in situations where the patient's hemodynamics are unstable. The oxygen mask should remain sealed over the patient's mouth for roughly 30 seconds or until fasciculations have ceased.

TABLE 15-3 The Definitions Used for Dosing

Weight description	Definition	Description	Alternative description
Total body weight (TBW)	The patient's weight		
Ideal body weight (IBW)	What the patient should weigh	$IBW\text{ (kg)} = \text{height (cm)} - X$ $X = 100$ for males $X = 105$ for females	Male IBW (kg) = $X + 2.3$ for every inch over 5 feet = $X = 50.0$ for males $X = 45.5$ for females
Lean body weight (LBW)	The patient's weight excluding fat (usually does not exceed 100 kg in men and 70 kg in women)	Male LBW (kg) = $\frac{9270 \times TBW\text{ (kg)}}{6680 + (216 \times BMI\text{ [kg/m}^2])}$ Female LBW (kg) = $\frac{9270 \times TBW\text{ (kg)}}{8780 + (244 \times BMI\text{ [kg/m}^2])}$	Male LBW (kg) = $(1.10 \times \text{weight [kg]}) - \frac{128 \times \text{weight}^2\text{ (kg)}}{(100 \times \text{height [m]})^2}$ Female LBW (kg) = $(1.07 \times \text{weight [kg]}) - \frac{148 \times \text{weight}^2\text{ (kg)}}{(100 \times \text{height [m]})^2}$
Adjusted body weight (ABW) or current body weight (CBW)	Obese patients have an increased lean body mass and volume of distribution	$ABW\text{ (kg)} = IBW\text{ (kg)} + 0.4 (TBW\text{ [kg]} - IBW\text{ [kg]})$	None
Morbid obesity	Severely overweight	$BMI > 40\text{ kg/m}^2$	$BMI > 35\text{ kg/m}^2$ with associated comorbidities

Follow the sedation with the depolarizing muscle relaxant succinylcholine. Succinylcholine should not be used in certain instances (Table 16-2). Use a nondepolarizing muscle relaxant (e.g., rocuronium) at a rapid sequence intubation dose if succinylcholine is contraindicated. **The Emergency Physician must have sugammadex available with a 16 mg/kg dose drawn at the bedside in case a “cannot intubate, cannot oxygenate” situation is discovered.**

Proceed with direct laryngoscopy. This will not be discussed here. Refer to the orotracheal intubation chapter (Chapter 18) for details.

DIFFICULT AIRWAY ALGORITHM

Difficult airways are common in obese patients. It can be a life-threatening situation when an Emergency Physician cannot successfully intubate an airway and has no systematic plan in place to prioritize the management. The Difficult Airway Society produced guidelines commonly known as the “Difficult Airway Algorithm.”⁴¹ The most recent revision was published in 2015. An algorithm for management of the obese airway is provided in Figure 15-4.

The Difficult Airway Society’s Difficult Intubation Guidelines consist of four separate plans in which the Emergency Physician

proceeds from one to the next if difficulty is encountered intubating or ventilating the patient. **Plan A is focused on maximizing the likelihood of successful intubation on the first attempt while limiting total attempts to prevent airway trauma.** It calls for proper patient positioning and preoxygenation. The recommendation is for three attempts at direct laryngoscopy by a single provider with one additional attempt by a more experienced person. Video laryngoscopes may be used.²⁵ Cricoid pressure should be applied throughout rapid sequence intubation unless there is difficulty intubating. **Repeated attempts at intubation should only occur if a change has been made to improve the chance of success (e.g., change of position, a different blade, neuromuscular blockade depth, or different personnel).**

The Emergency Physician should proceed to Plan B if attempts at Plan A have been exhausted. **Plan B emphasizes the importance of maintaining oxygenation using a supraglottic airway device (SAD).** Use a SAD to buy time and allow the Emergency Physician to assess the situation while the patient can be adequately ventilated. Use second-generation SADs due to various design improvements (e.g., the ability to intubate through the device).^{12,42-44} A total of three attempts at placing a SAD is recommended, with the third attempt using a

FIGURE 15-3. The Howland Lock. **A.** The Howland Lock. **B.** The Howland Lock attached to a laryngoscope.

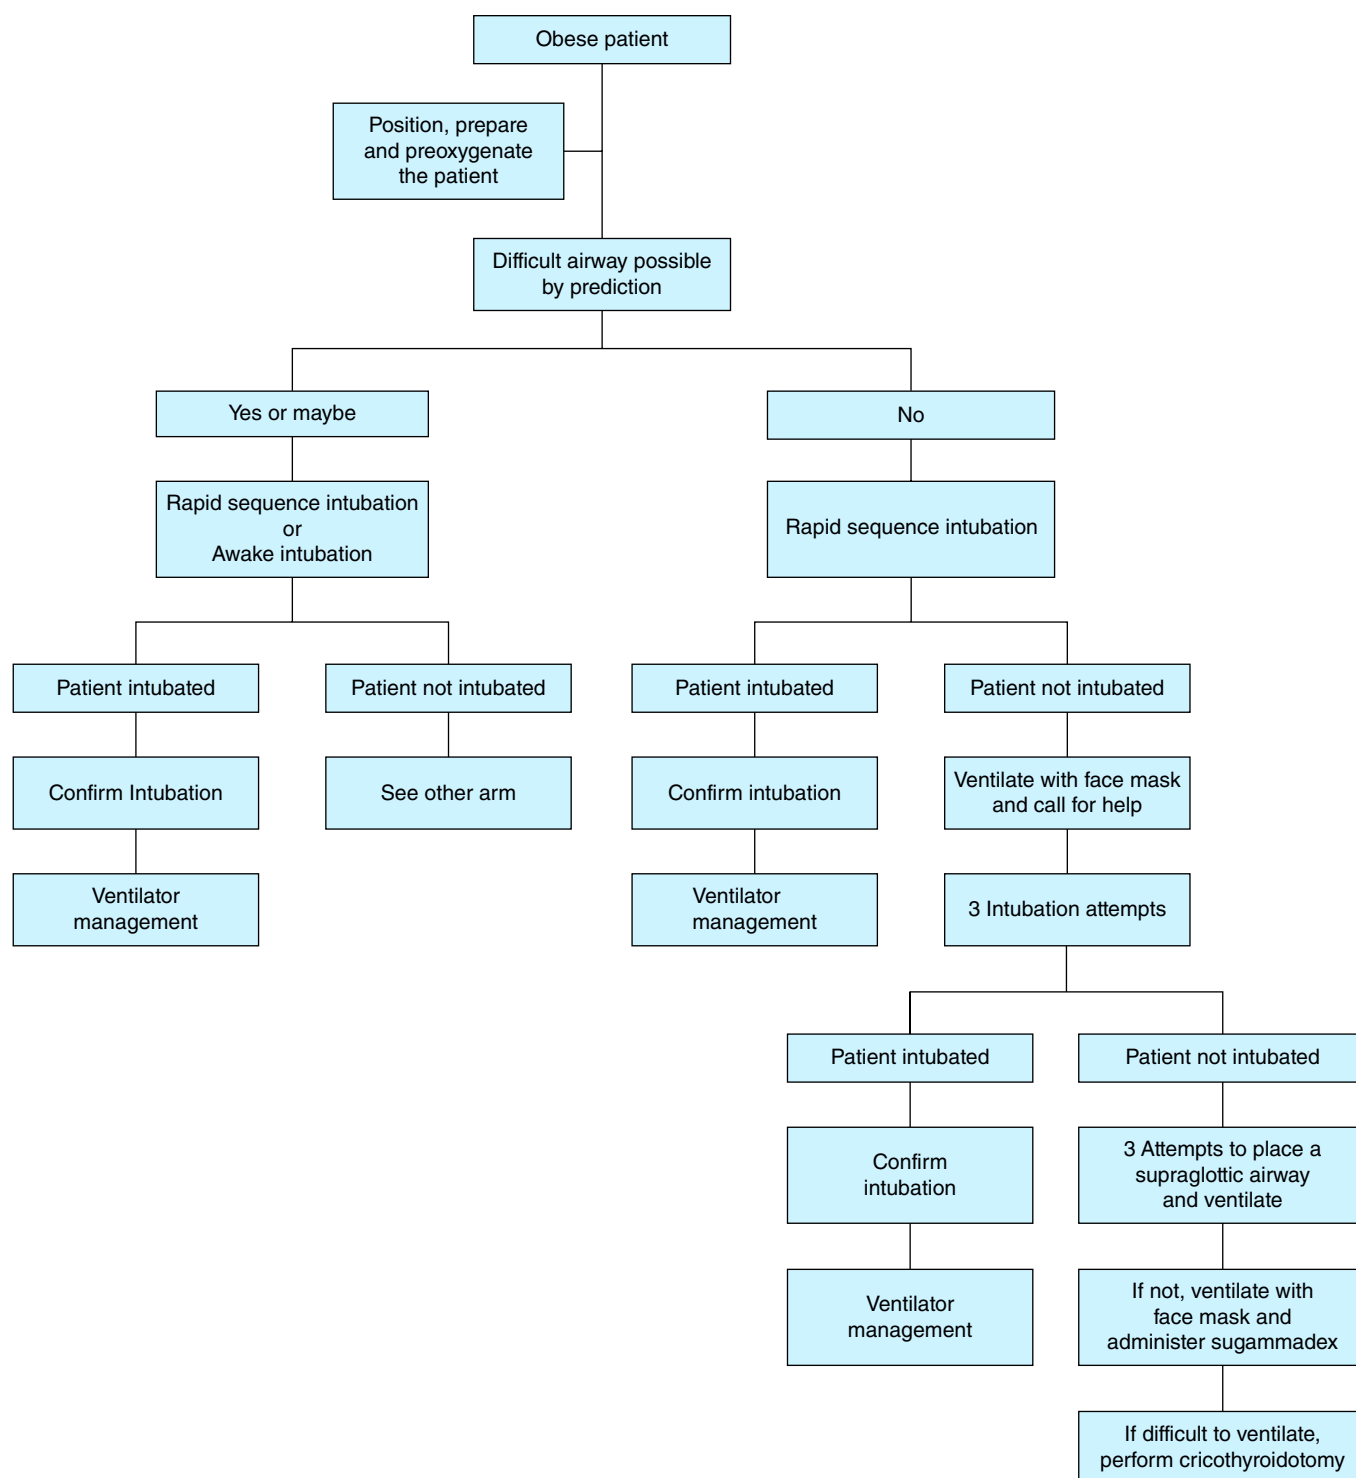

FIGURE 15-4. A suggested algorithm for the management of the obese airway.

different type or size. **Additional attempts are not recommended because SAD placement can induce airway trauma and swelling.** Successful SAD placement requires further reflection. The Emergency Physician should decide whether to wake the patient, attempt to intubate through the SAD, or proceed with a surgical airway.

The Emergency Physician should proceed to Plan C if attempts at Plan B have been exhausted. **Plan C is a final attempt to ventilate the patient with a face mask.** Maintain oxygenation and wake the patient up if mask ventilation is possible. The patient's airway can be traumatized, making mask ventilation much more difficult. Administer sugammadex at a dose of 16 mg/kg if mask ventilation

is possible for a full reversal in the "cannot intubate, cannot oxygenate" scenario.⁴⁵

The Emergency Physician should proceed to Plan D if attempts at Plan C have been exhausted. **Plan D is officially declaring the patient "cannot intubate, cannot oxygenate" and proceeding with a surgical airway.** Hypoxic brain injury will ensue and potentially patient death if the situation is not rapidly changed. Proceed with a surgical airway (Chapter 32) while two-person ventilation attempts are continued. One person uses two hands to apply the jaw-thrust and extend the patient's head, while another person delivers breaths with the bag-mask device.

ASSESSMENT

Evaluation of a successful endotracheal intubation should be fast and accurate. The time to desaturation in the obese patient is significantly shorter than the nonobese patient. Only relevant topics will be discussed.

The most common mistake made is removing eye contact of the glottis prematurely following what was thought to be a successful intubation. The intubator has the best ability to confirm intubation with direct visualization of the endotracheal tube passing through the vocal cords. It is common to see the tip of the endotracheal tube at the vocal cords and simultaneously advancing it while removing the laryngoscope. This is often performed to quickly to attach the bag-mask device. The ability to see the laryngeal aperture clearly in obese patients is poor. Their crowded pharynx allows less room to manipulate the endotracheal tube while maintaining an unobstructed view. **Eye contact should never be taken off the vocal cords from the first moment they are brought into view. Visualize the endotracheal tube cuff advancing completely past the vocal cords.** If only the portion of the endotracheal tube distal to the cuff is seen at the vocal cords, it can become caught in the arytenoid cleft and proceed into the esophagus. The Emergency Physician is likely to believe in and reassure the team of a successful intubation without direct visualization.

Confirm the placement of the endotracheal tube. Give three to four medium-sized breaths and watch for continuous and complete color change of the CO₂ colorimetric device. Instruct an assistant to auscultate the left subcostal region for gastric breath sounds and both sides of the chest for lung sounds. Watch for bilateral chest rise and condensation on the inside the entire endotracheal tube, and listen for an air leak with the application of breaths. Chest rise may not always be seen in obese individuals, but any movement should be symmetrical. Condensation can be mistaken if air from the esophagus is projected back onto the outside of the endotracheal tube. An air leak is important to assess because an intubated esophagus commonly gives a “gurgling” sound with each breath. Refer to Chapter 19 for a more complete discussion of the confirmation of endotracheal intubation.

This entire assessment should take no more than 10 seconds. **Look with the laryngoscope immediately to try to visualize the endotracheal tube position if an esophageal intubation is suspected.** Remove the endotracheal tube immediately and proceed with mask ventilation or Plan B of the difficult airway algorithm if the patient's saturations continue to fall or esophageal placement is confirmed.

AFTERCARE

There is very little to guide the Emergency Physician on ventilator management of the obese patient. Attach the endotracheal tube to a ventilator (Chapter 36). The Emergency Physician tends to lie the patient down. **Keep the head of the bed elevated 30° to 45° to displace the abdomen and improve ventilation.** This position also decreases the aspiration risk. Apply positive end expiratory pressure (PEEP) so the chest wall does not collapse the airways.²⁰ Keep the tidal volume based on the patient's ideal body weight to decrease the chance of inappropriate ventilator settings.²⁰ **Remember to sedate the patient after intubation. Do not paralyze the patient without sedation.**

COMPLICATIONS

Many of the complications encountered while intubating an obese patient are similar to those of the nonobese patient. Refer to Chapter 18 for a complete discussion of the complications

associated with orotracheal intubation. Obese patients are at an increased risk for aspiration, which is discussed in greater detail below.^{1,21} **Quick and efficient handling of aspiration is vital to the patient's survival.**

Obese patients are at an increased risk of aspiration, especially with full stomachs. **Perform an awake fiberoptic or awake indirect laryngoscopy to minimize the risk of aspiration.** Succinylcholine is the paralytic of choice for multiple reasons. It has a very rapid onset and is short acting. Succinylcholine increases the tone of the lower esophageal sphincter and further minimizes the risk of emesis. Cricoid pressure has been shown to decrease the tone of the lower esophageal sphincter. Several reports and studies have been performed weighing the risk versus benefit of cricoid pressure. The use of this maneuver is controversial, but it is used widely and the risks versus benefits should be known to all Emergency Physicians.⁴⁶ The common practice is to use cricoid pressure for rapid sequence intubation, with adjustments directed by the intubating provider.

Immediately apply cricoid pressure if aspiration occurs at any point, even if cricoid pressure has been released. **Direct the Yankauer suction catheter toward the posterior pharynx to clear as much emesis as possible.** Instruct an assistant to position the bed in Trendelenburg to minimize the flow of emesis into the trachea. Do not remove the laryngoscope if it is in the patient's mouth as the best protection from aspiration is to quickly intubate. Inflate the cuff immediately once intubated. Apply breaths if the saturation is below 80%. Proceed with endotracheal suctioning if the saturation is above 92% to remove tracheal aspirate prior to positive-pressure breaths. Perform a fiberoptic examination to completely assess the airway once the patient is properly oxygenated. Consult an Anesthesiologist or Pulmonologist if large particulate matter is seen or deep bronchial lavage is needed.

SUMMARY

Obesity is becoming an exceedingly common problem in the United States. It adds many challenges for the Emergency Physician when managing the airway. Changes are seen in anatomic variations and physiologic variations. This further stresses the importance of experience and knowledge needed to safely manage these patients. Obese patients are at higher risk of having a difficult airway. Advanced airway equipment must be available along with the capability for a surgical airway. Special emphasis must be given to proper patient positioning and technique because the time to desaturation is significantly decreased in the obese patient. Awareness of medication pharmacodynamic and pharmacokinetic differences in obesity is necessary for accurate and safe intubation. Assessments of successful intubations must be fast and thorough with obese patients to avoid the increased risk of morbidity and mortality.

Rapid Sequence Intubation

Ned F. Nasr, Piotr Aljindi, and Isam F. Nasr

INTRODUCTION

Rapid sequence intubation (RSI) of anesthesia is sometimes referred to as a "crash" intubation. The definition of RSI is the near simultaneous administration of a neuromuscular blocking drug and a sedative to induce unconsciousness and paralysis for endotracheal intubation. It has become a safe and effective method of establishing emergent airway control in patients with suspected life-threatening emergencies. It ensures optimal patient compliance in the best possibly controlled environment that can be achieved in the Emergency Department (ED). RSI in its classical description involves preoxygenation followed by the near simultaneous administration of a potent sedative-hypnotic agent and a neuromuscular blocking agent, application of cricoid pressure, avoidance of positive-pressure ventilation by mask, and intubation with a cuffed endotracheal tube.¹⁻²¹ Various pretreatment drug regimens have been advocated to prevent the potentially deleterious side effects of aspiration of gastric contents, cardiovascular excitation or depression, and intracranial pressure elevation.

The first endotracheal tubes were developed for the resuscitation of the newborn and victims of drowning in the 19th century but were not used in anesthesia until 1878.¹³ Muscle relaxants were not prepared until some 60 years later. Succinylcholine was prepared by the Nobel Laureate Daniel Bovet in 1949, after which it gained the widespread usage it still enjoys today. The RSI technique did not come into modern-day practice until the end of World War II.

Patients can be hypoxic, confused, uncooperative, unstable, and unknowing of their medications or medical conditions and can require airway control within minutes of arrival at the ED. RSI is

the preferred method for securing the airway in the ED, as these patients are at risk for aspiration. These risks include vomiting from gastrointestinal obstruction, opioids, or hypotension; regurgitation from diabetic gastroparesis, gastroesophageal reflux, increased gastric pressure, or decreased lower esophageal sphincter tone; impaired laryngeal protective reflexes; and difficult airway management.⁷ Conditions such as recent meal ingestion, pain, obesity, and pregnancy place patients at higher risk as well.

The procedure of RSI has many steps. It is sometimes easier to remember the 10 P's of RSI: plan, preparation (of drugs, equipment, and people), protect the cervical spine (if indicated), positioning (can be done after paralysis), preoxygenation, pretreatment (e.g., atropine, fentanyl, lidocaine), paralysis, protection (i.e., Sellick's maneuver), placement (endotracheal tube and confirmation of its position), and postintubation management. The controversy surrounding the technique (e.g., cricoid pressure effectiveness and ventilation prior to intubation) and the role in preventing aspiration has been questioned.²²⁻²⁵ This has contributed to the lack of standardization.²²⁻²⁵ Despite this, RSI has currently achieved a status close to being a standard of care for ED intubation in patients with full stomachs.²⁴

INDICATIONS

The primary indication for RSI is to quickly protect and secure the patient's airway, preventing regurgitation of gastric content, and preventing aspiration. The rationale behind RSI is to create an environment in which the trachea can be intubated as quickly and with as little difficulty as possible. The clinical conditions occurring at the time of attempted intubation are therefore of great importance. The drugs used to produce hypnosis and muscle relaxation interact together to produce intubating conditions individualized to the patient and their condition(s). A complete list of the indications for RSI appears in **Table 16-1**. Other indications for RSI include

TABLE 16-1 Indications for RSI in the Emergency Department
Airway protection and risk for pulmonary aspiration (e.g., full stomach, pregnancy, and obesity)
Altered mental status
Application of advanced cardiac life support and administration of drugs
Clinically declining patient
Definitive maintenance of airway patency
Depressed level of consciousness and questionable ability to maintain a patent airway
Emergency surgery and requirement for general anesthesia
Facilitation of fiberoptic bronchoscopy
Full stomach or unknown stomach contents
Head trauma with a decreased Glasgow Coma Scale score
Head trauma with the need for airway control
Head trauma with the need for ventilation
Hypothermia management
Hypoventilation
Impending airway obstruction (e.g., burns or penetrating neck injury)
Increased oxygen consumption
Increased oxygen delivery
Increased work of breathing
Potentially difficult intubation after airway evaluation
Prevention of brain hypoxemia
Pulmonary toilet or secretion management
Respiratory failure, actual or impending
Status epilepticus
Transfer of patient between facilities
Uncontrolled seizure activity requiring airway control
Uncooperative or combative patient with compromised airway
Unresponsiveness

Source: Adapted from references 2 and 7.

to control ventilation in the intubated patient, to control agitation, to control seizures, and to facilitate the patient workup.

The drugs are used to attenuate the response to intubation, blunt perception, blunt recall, decrease adverse effects, make intubation easier, and make intubation more controlled. Some patients inadequately respond to paralysis or have a prolonged paralysis. A decrease in neuromuscular blockade with rocuronium and succinylcholine is seen with hypercalcemia. Chronic use of carbamazepine or phenytoin may show resistance to rocuronium. A prolonged neuromuscular blockade with rocuronium and succinylcholine is seen with acidosis, aminoglycoside antibiotics, hypermagnesemia, hypokalemia, and hypothermia. Severe hepatic dysfunction may decrease the metabolism of rocuronium and result in a more prolonged paralysis.

Nondepolarizing neuromuscular blocking agents are usually used in the ED for RSI. A few specific situations deserve mention. These agents are safe in epilepsy, Parkinson's disease, and stroke. More of the agent is required if the patient has myasthenia gravis and its effects last longer. Less of the agent is required with Eaton-Lambert syndrome, hypothyroidism, and organophosphate poisoning.

CONTRAINDICATIONS

There are few contraindications to RSI. It should not be performed by an inexperienced intubator. Consider an awake intubation or surgical airway if the Emergency Physician has doubts about their ability to intubate the patient. The unavailability of equipment, contraindications to muscle relaxants, and critically ill patients in whom the airway can be secured by other methods (e.g., fiberoptic intubation, topical anesthesia, or minimal sedation with a benzodiazepine and/or narcotic) are also contraindications to RSI. Any contraindication to the use of succinylcholine is also a contraindication to RSI. **Table 16-2** lists the many common contraindications to the use of succinylcholine. Patients in cardiopulmonary arrest do not require RSI as they should not have any muscle tone to overcome. A relative contraindication is a patient in whom bag-valve-mask

TABLE 16-2 Contraindications to the Use of Succinylcholine
Cardiac arrhythmia
Children and adolescents, unless no other option exists
Exaggerated hyperkalemia in susceptible patients
Crush injuries
Denervation beyond 48–72 h after injury ¹⁴
Disuse atrophy
More than 24 hours after major burns and trauma
Metastatic rhabdomyosarcoma ¹⁴
Muscular atrophy
Paraplegia or hemiplegia
Prolonged immobilization
Severe abdominal infection
Guillain-Barré syndrome
History of malignant hyperthermia in the patient or in their family history
Hypersensitivity to the drug
Increased intracranial pressure (relative)
Increased intragastric pressure (relative)
Increased intraocular pressure (relative)
Masseter muscle spasm or rigidity
Motor neuron disease
Muscular dystrophy
Plasma cholinesterase deficiency (relative)
Skeletal muscle myopathies in the patient or in their family history
Spinal cord injury

Source: Adapted from references 1, 2, 8, and 14.

ventilation is difficult or anticipated to be difficult.^{26,27} Other relative contraindications are a team with poor skills or that functions poorly, the anticipated difficult airway, children less than 5 years of age, patients with distorted upper airways (e.g., congenital or acquired), situations when a surgical airway is not possible (e.g., lack of equipment or lack of experience), and patients with an upper airway obstruction.

EQUIPMENT

- Supplemental oxygen with appropriate tubing and connectors
- Laryngoscope handle with extra batteries
- Laryngoscope blades, various sizes and types
- Video laryngoscope
- Endotracheal tubes, various sizes
- Wire stylet, malleable type
- Nonrebreather oxygen masks, various sizes
- Oropharyngeal airways, various sizes
- Nasopharyngeal airways, various sizes
- Alternative airway devices
- Suction source with appropriate tubing
- Suction catheters for endotracheal tubes
- Yankauer suction catheter
- Bag-valve-mask devices, various sizes
- Face masks, various sizes
- Stethoscope
- Water-soluble lubricant or anesthetic jelly
- Tape
- Benzoin adhesive
- Syringes, 10 and 20 mL
- Medications drawn up and labeled
- Pulse oximeter
- Cardiac monitor
- Automatic sphygmomanometer
- End-tidal carbon dioxide (CO₂) monitor/device
- Crash cart
- Resuscitation medications
- Personnel (respiratory technician, medication nurse, recorder, in-line stabilization assistant)

The equipment required for RSI is the same as that for any intubation.^{10,13} Complete details regarding the selection of properly sized equipment can be found in Chapters 10 and 18. **Backup equipment should be readily available if the patient cannot be intubated.** This can be a laryngeal mask airway, cricothyroidotomy tray, retrograde guidewire kit, or percutaneous jet ventilation system, to name a few.

PATIENT PREPARATION

RSI can be performed with little or no preparation. A few steps can be performed while the patient is being evaluated. Administer supplemental oxygen to the patient with a nonrebreather mask, continuous positive airway pressure (CPAP) mask, or noninvasive nasal positive-pressure ventilation (NINPPV). Apply a noninvasive blood pressure cuff, continuous pulse oximetry, and cardiac monitoring. Obtain intravenous (IV) or intraosseous access.²⁸ If time permits, pharmacologic agents can be used to increase gastric

pH and motility (e.g., antacids, H₂-receptor blockers, and metoclopramide). An antisialagogue (e.g., atropine or glycopyrrrolate) may also be administered to decrease excessive oral and respiratory tract secretions.

What is the ideal RSI agent? It has the following characteristics: provides analgesia and amnesia, short onset, predictable length of time to work and last, maintains hemodynamics, maintains cerebral perfusion pressure, causes unconsciousness and unresponsiveness, and has few side effects. **No single agent exists. We use multiple agents to minimize side effects and maximize the effects we want.**

Evaluate the airway. Long teeth and buck teeth are problematic and affect the angle of the laryngoscope blade. The mandibular teeth should move in front of the maxillary teeth to test the motion of the temporomandibular joint (TMJ). There should be 3 cm between the mandibular teeth and maxillary teeth upon mouth opening. Look at the size of the tongue to see if it is enlarged (i.e., Does the tongue obscure the pharyngeal structures?). Ensure the palate is not too narrow and there is room for the laryngoscope blade and endotracheal tube. Check to see if there are three finger breadths between the chin and the thyroid cartilage. Determine if the neck is short, long, and/or thick. The patient should be able to assume the sniffing position. Finally, is there any resistance to movement of the front of the neck? **Any deviation from the “normal” can signify a potentially difficult airway. If, after evaluation of the airway, there is sufficient doubt as to the possibility of intubating the patient successfully, a neuromuscular relaxant should not be administered. Consideration should be given to securing the airway in another fashion (e.g., awake intubation).**

TECHNIQUE

The three main characteristics of RSI are **preoxygenation, application of cricoid pressure, and avoidance of positive-pressure ventilation if possible prior to securing the airway with a cuffed endotracheal tube.** In addition, RSI requires the presence of ancillary equipment and experienced assistance. The details of timing, drug choice, and dosage are not rigidly defined. An RSI protocol is described below from start to finish.

Preoxygenate the patient with 100% O₂ by nonrebreather mask, or ventilate with a bag-valve-mask device using cricoid pressure. This will build an oxygen reserve and prevent hypoxemia during intubation. Preoxygenation for 5 minutes is the routine practice. If this is not practical, attempt to preoxygenate the patient for 3 minutes.⁶ However, four maximal inspirations are equally effective in the cooperative patient.⁶ A recent study has shown that eight vital capacity breaths in 1 minute provide a better safety margin with almost double the apneic time without hypoxia compared with 3 minutes of tidal volume breathing.²⁹ Oxygen administration via noninvasive positive-pressure ventilation can improve oxygenation more rapidly than by a face mask.³⁰ Utilization of CPAP or NINPPV during the preoxygenation has been shown to increase the duration of the apneic period without hypoxemia.^{31–33} In addition, head elevation of 20° to 25° has been shown to improve oxygenation as well.³⁴ Preoxygenation often eliminates the need for positive-pressure ventilation in RSI.³⁵

Consider apneic oxygenation during the period of preoxygenation and paralysis.^{36–39} This can be provided by using a nasal cannula at 15 L/min. The diaphragm does not have to move for gas exchange at the alveoli. Its use has shown mixed results in terms of eliminating hypoxemia during RSI.

While an assistant is preoxygenating the patient, evaluate the airway to anticipate any difficulties during the intubation. Assemble all required equipment. Connect the bag-valve device to a mask and

TABLE 16-3 Pharmacologic Adjuncts to Intubation in the Premedication Phase

Agent	Standard dose	Trauma dose	Blood pressure	Cerebral perfusion pressure
Fentanyl ^a	2.0–8.0 µg/kg	1.0–3.0 µg/kg	Stable	Stable
Sufentanil ^a	0.25–µg/kg	0.1–0.2 µg/kg	Stable	Stable
Alfentanil ^a	5.0–25.0 µg/kg	5 µg/kg	Stable	Stable
Remifentanyl ^a	0.25–1.0 µg/kg/min	0.05–0.5 µg/kg/min	Stable	Stable
Lidocaine ^b	1.0–1.5 mg/kg	1.0–1.5 mg/kg	Stable	Stable or increased

^aMinimal hemodynamic or cerebrovascular effects. Useful agents for blunting the noxious stimuli of direct laryngoscopy or intubation. The half-time of equilibration between the effect and plasma is relatively slow (5 to 6 minutes). May cause central vagal stimulation with resultant bradycardia and occasionally hypotension in patients with high sympathetic tone.

^bSimilar to fentanyl, but more potent and faster offset.

^cSimilar to fentanyl, but faster onset and duration of action. Half-time of equilibration between the effect site and the plasma is 1.5 minutes, making this opioid a very appropriate drug to provide a transient peak effect after a single bolus dose. May prevent the increase in intraocular pressure caused by succinylcholine.⁸

^dSimilar to alfentanil in terms of fast onset. Extremely rapid clearance (3 to 4 L/min) due to esterase metabolism, resulting in a rapid and predictable recovery.

^eUseful adjuvant agent for blunting airway reflexes. Also blunts blood pressure, intracranial pressure, and intraocular pressure responses to intubation, involuntary muscle movements after etomidate, and injection site pain from propofol and etomidate. Topical lidocaine is also effective in blunting reflexes.

Source: Adapted from Chapter 12.

an oxygen supply. Lubricate and place the malleable stylet into the endotracheal tube. Attach a syringe to the inflation port of the endotracheal tube cuff. Inflate the cuff to look for any air leaks. Deflate the cuff and leave the syringe attached to the inflation port. Attach the laryngoscope blade to the handle and make sure that the light is functional.

Simultaneously, the nurses should apply a noninvasive blood pressure cuff, continuous pulse oximetry, and cardiac monitoring to the patient. They should also draw up and label the required medications, establish intravascular access, set up the suction, record all events, and continuously observe the noninvasive blood pressure readings, cardiac monitor, and pulse oximeter.

If there is no suspicion of a cervical spine injury, position the patient in the optimum “sniffing” position. If there is suspicion of a cervical spine injury, an assistant should provide manual in-line axial stabilization of the head and neck during the intubation sequence. Remove the anterior aspect of the cervical spine collar to allow for maximal mouth opening and access to the neck.

Premedicate the patient (Table 16-3). The mnemonic **LOAD** has been used to indicate the pretreatment drugs for RSI.¹⁵ The mnemonic stands for lidocaine, opioid (specifically, fentanyl), atropine, and defasciculation. Lidocaine (1.0 to 1.5 mg/kg) can be given to blunt the intracranial pressure response, transient hypertension, bronchospasm, and tachycardia associated with intubation. Fentanyl (2 to 3 µg/kg) or one of its derivatives can be given to also blunt the intracranial pressure response, transient hypertension,

and tachycardia associated with intubation. Atropine (0.01 to 0.02 mg/kg; minimum 0.1 mg, maximum 1.0 mg) should be given to children less than 1 year old to prevent bradycardia in response to direct laryngoscopy. Administer a defasciculating dose of a non-depolarizing neuromuscular blocking agent. This is one-tenth of the intubating dose (Table 16-4). Phenylephrine (50 µg) can be given to attenuate the hypotensive response to intubation. Administer an appropriate induction agent as indicated by the clinical setting and patient’s hemodynamic status (Tables 16-5 and 16-6). Flush the intravenous line with 10 to 20 mL of 0.9% normal saline solution after each drug to ensure delivery.⁴⁰

Administer a neuromuscular blocking agent.^{1,2,5} Numerous agents are available (Table 16-4). The most commonly used medications are succinylcholine (1.0 to 1.5 mg/kg) or rocuronium (1.0 to 1.2 mg/kg). **Some consider succinylcholine the preferred agent. Its effects are short-lasting (i.e., 4 to 6 minutes). This is especially useful if the patient cannot be intubated, as he or she will need to be ventilated with a bag-valve-mask device until the succinylcholine wears off.** Rocuronium allows the same intubating conditions as succinylcholine except that it lasts for 30 to 60 minutes, causes no fasciculations, and causes no histamine release. This long-lasting time frame is problematic if the patient cannot be intubated. Rocuronium (1.2 mg/kg) delivers a rapid onset of paralysis similar to succinylcholine.⁴¹ A Cochrane Review concluded that succinylcholine was superior to rocuronium in achieving excellent and clinically acceptable intubating conditions.⁴²

TABLE 16-4 Selected Pharmacologic Properties of the Neuromuscular Relaxants

Agent	Intubation dose (mg/kg)	Average intubating time (min)	Clinical duration (min)	Comments
Succinylcholine	Children: 2 mg/kg Adults: 1 mg/kg ¹⁶ IM: 4 mg/kg	1	4–6	Agent used for RSI. ^{1,2} Associated with side effects such as exaggerated hyperkalemia in susceptible patients (> 24 hours after major burns and trauma, crush injury, denervation, prolonged immobilization, paraplegia, hemiplegia, muscular dystrophy) and malignant hyperthermia. Elevates intraocular, intracranial, and intragastric pressures. Use the total body weight (not the lean weight) even in the morbidly obese or pregnant patient.
Rocuronium	0.6–1.2 Children 2 to 12 years old: 0.9–1.2 ¹⁷	0.7–1.1	31–67	An alternative to succinylcholine provided there is no anticipated difficulty in intubation. ⁴
Vecuronium	0.08–0.10	2.5–3.0	25–40	Cardiovascular effects unlikely. Alternative to succinylcholine.
Cisatracurium	0.15–0.20	1.5–2.0	55–65	Stereoisomer of atracurium. No cardiovascular effects. Organ-independent elimination.
Atracurium	0.4–0.5	2.0–2.5	35–45	Elimination independent of liver and kidney. Releases histamine.
Pancuronium	0.06–0.10	2.0–3.0	56–100	Tachycardia and sympathetic nervous system activation.

TABLE 16-5 Pharmacology of the Anesthetic Induction Agents

Agent	Dose (mg/kg)	Steady-state volume of distribution (L/kg)	Clearance (mL/min/kg)	Elimination half-life (h)
Thiopental	Adults: 3.0–5.0 Children: 3.0–5.0 Infants: 7.0–8.0 ¹⁸	2.5	3.4	11.6
Etomidate	0.2–0.3	2.5–4.5	10.0–20.0	2.0–5.0
Propofol	Adults: 1.5–2.5 Children 3.0–6.0	2.0–10.0	59.4	4.0–7.0
Midazolam	0.1–0.2	1.0–1.5	7.5	1.0–4.0
Ketamine	1.0–2.0	2.5–3.3	16.0–18.0	1.0–2.0
Methohexital	1.0–3.0	0.4	6.56	22 days
Fentanyl	0.002–0.02	4.0	4.8–10.5	3.5–4.0

Source: Adapted from references 3, 7, 8, and 18.

The U.S. Food and Drug Administration (FDA) approved sugammadex in the United States in 2015. It has been available in other parts of the world for several years. It binds to rocuronium and prevents the rocuronium from binding to nicotinic receptors and inducing neuromuscular blockade. Sugammadex works in approximately 30 minutes. It is not metabolized and is excreted unchanged in the urine in about 8 hours. The argument of succinylcholine being the preferred agent due to its short-lasting action no longer exists. Sugammadex not only more predictably antagonizes muscle relaxation induced by rocuronium than spontaneous recovery from succinylcholine, but the reversal time is faster too.^{33,43–45} The typical dose is 2 to 4 mg/kg. Up to 16 mg/kg can be given if quick reversal of rocuronium is needed. The use of sugammadex has not been studied in pregnancy and lactation. A recent survey of Anesthesiologists in the United Kingdom showed that succinylcholine is still the most common used agent for RSI.²⁵

An assistant should apply cricoid pressure with a force of 20 to 30 Newtons as soon as the patient loses consciousness and maintain it until successful oral endotracheal intubation has been confirmed. How much force is a Newton? It is difficult to translate from mechanical devices to the human hand. A discussion of the use of cricoid pressure is in Chapter 18. Avoid mask ventilation if possible. If hypoxemia or hypercarbia ensues, begin mask ventilation to a maximum pressure of 20 cmH₂O while maintaining cricoid pressure.

Intubate the trachea 60 to 90 seconds after the succinylcholine (or rocuronium) has been administered and the patient's muscles are relaxed, as noted by apnea and jaw relaxation. **Confirm the correct position of the endotracheal tube by visualizing the tube passing through the vocal cords, observing sustained presence of end-tidal CO₂ on the capnograph, and auscultating breath sounds at the midaxillary lines.**^{11,12} Auscultate over the epigastric area to ensure that ventilation is not audible over the stomach. Release the cricoid pressure. If indicated, administer a long-acting paralytic agent (Table 16-4). After successful intubation, administer

additional sedative hypnotics and analgesics as dictated by clinical need. Obtain a chest radiograph to confirm proper placement of the endotracheal tube.

PEDIATRIC CONSIDERATIONS

RSI is often used in the Emergency Department for securing the airway of pediatric patients. The indications and equipment, except for being smaller, are essentially no different than those of the adult patient. Infants and young children have developmental differences in head and neck anatomy. These differences make the Miller blade the preferred laryngoscope blade for intubation in this group. Infants and young children have a higher volume of distribution, which is why they require different doses of induction agents, as reflected in Tables 16-4 and 16-5.

Preoxygenation is particularly important for infants and children. Compared with adults, these young patients have a higher oxygen consumption rate with lower functional residual capacity. Consequently, oxygen desaturation occurs much more rapidly (i.e., 1 to 2 minutes in healthy infants and 2 to 4 minutes in healthy children). Perform careful bag-mask ventilation with small tidal volumes while maintaining cricoid pressure to achieve adequate preoxygenation if the child is desaturating or is apneic.

The use of succinylcholine remains controversial in pediatrics. RSI and laryngospasm are perhaps the last remaining indications for the use of succinylcholine in pediatrics. In 1994, the FDA recommended that the use of succinylcholine in children be reserved for emergency intubation and instances where the immediate securing of the airway is necessary due to the risks of hyperkalemia. This includes patients with laryngospasm, difficult airways, or full stomachs, or for intramuscular use. If a child has no vascular access, succinylcholine (4 mg/kg) can be administered intramuscularly. It will provide a maximum onset of blockade in 3 to 4 minutes and last approximately 20 minutes. If there is a contraindication to using succinylcholine, rocuronium can be used for RSI. Children between

2 and 12 years old require more rocuronium than adults. The recommended doses are 0.9 to 1.2 mg/kg in this age group.

Atropine is commonly used in young children. Atropine (20 µg/kg) administered as a premedication is indicated in all children < 1 year old and in all ages if a second dose of succinylcholine is required to intubate the patient.¹⁹ There is a risk of bradycardia with the use of succinylcholine in children. This can be attenuated by premedicating the patient with atropine (20 µg/kg) or glycopyrrolate (10 µg/kg).²⁰

TABLE 16-8 Mnemonics for RSI Preparation**SOAPME**

- Suction
 - At least one working suction
 - Two suctions for gastrointestinal bleeds, vomiting, or lots of secretions
 - Yankauer suction catheter placed between mattress and head of bed
- Oxygen
 - Nonrebreather mask and bag-valve device attached to 15 L/min O₂
 - ? Nasal cannula for apneic oxygenation
- Airways
 - Oral and nasal airways
 - Endotracheal tubes with stylets, balloon tested
 - Stylet inside endotracheal tube and bent 30°
 - Laryngoscope handles and blades, light tested
 - Video laryngoscope
 - Cricothyroidotomy kit as backup
 - Backup devices (e.g., bougie, laryngeal mask airway, supraglottic airway, etc.)
- Preoxygenate and positioning
 - Nonrebreather mask at 15 L/min O₂
 - Sniffing or ear to sternal notch
 - Ramp or blankets for obese patients
- Monitoring equipment and medications
 - Cardiac monitor, noninvasive blood pressure cuff, pulse oximeter, IV line
 - Medications drawn into syringes and labeled for RSI and postintubation sedation
- End-tidal CO₂ and other equipment
 - End-tidal CO₂ monitor or colorimetric device

O₂ MARBLES

- Oxygen
- Masks (e.g., nonrebreather and bag-valve-mask) and medications
- Airway adjuncts, ask for help, and airway cart for difficult airways
- RSI drugs and resuscitation drugs
- Bag-valve-mask and bougie
- Laryngoscopes (e.g., direct and video) and laryngeal mask airway
- Endotracheal tubes and end-tidal CO₂ detection
- Suction and state plan

ASSESSMENT

Confirm that endotracheal intubation is successful. Success is indicated by auscultation, fogging of the endotracheal tube with ventilations, and the presence of persistent end-tidal CO₂. End-tidal CO₂ can be confirmed using a capnograph or a chemical colorimetric indicator device, which consists of a pH-sensitive indicator where the dye changes its color in the presence of CO₂. A minimum of six breaths should be administered before a determination is made regarding successful endotracheal intubation. This will eliminate false-positive readings obtained by CO₂ forced into the stomach during mask ventilation, antacids in the stomach, or carbonated drinks in the stomach. False-negative results may be seen with very low tidal volumes and low end-tidal CO₂ concentrations during severe hypotension or cardiac arrest. During cardiopulmonary resuscitation (CPR), a negative result requires an alternative method of confirming the position of the endotracheal tube because compromised circulation causes low end-tidal CO₂.¹² Other methods used to confirm endotracheal intubation include fiberoptic endoscopy with direct visualization of the tracheal rings and carina, pulse oximetry (low saturation is a late sign for esophageal intubation), blood gas analysis, chest radiography, and a variety of detection devices. Please refer to Chapter 19 for more information regarding the confirmation of endotracheal intubation.

AFTERCARE

The aftercare is the same as for any intubated patient. Secure the endotracheal tube with tape or a commercially available

TABLE 16-9 A Sample RSI Protocol

- Zero minus 10 minutes
 - Preparation
 - Assess airway for difficulty

- ☐ Preoxygenation
- ☐ Apneic oxygenation
- ☐ Assess airway for potential difficulty
- ☐ Call for help if difficulty is determined
- ☐ Vascular access obtained
- ☐ Vascular access flushes
- ☐ Patient positioning
- ☐ How will anesthesia be maintained?
- ☐ Explain process to patient

Prepare Equipment

- ☐ Electrocardiogram applied
- ☐ Blood pressure cuff applied
- ☐ Blood pressure cuff set for 2-minute cycles
- ☐ Pulse oximetry applied and working
- ☐ End-tidal CO₂ monitor or colorimetric device
- ☐ Bag-valve-mask, correct size for patient
- ☐ Suction set up from wall to Yankauer
- ☐ Suction turned on and working
- ☐ Multiple endotracheal tubes and stylets
- ☐ Endotracheal tube cuff tested
- ☐ Multiple laryngoscope handles and blades
- ☐ Video laryngoscope and working
- ☐ Multiple syringes, various sizes
- ☐ Bougie
- ☐ Difficult airway cart at bedside
- ☐ List of drugs available
- ☐ Syringes with drugs and labeled
- ☐ Confirmed drug doses

Prepare the Team

- ☐ Identify team leader
- ☐ Identify intubator
- ☐ Identify Sellick's holder
- ☐ Identify in-line cervical stabilizer, if applicable
- ☐ Identify drug preparer
- ☐ Identify drug administrator
- ☐ Identify recorder of record
- ☐ Describe the plan

The Procedure

- ☐ Administer premedication
- ☐ Administer sedation
- ☐ Administer neuromuscular blocker
- ☐ Allow neuromuscular blocker to work
- ☐ Laryngoscopy
- ☐ Insertion of endotracheal tube
- ☐ Abort laryngoscopy if time runs out, pulse oximetry drops, or unsuccessful
- ☐ Call for help
- ☐ Secure endotracheal tube
- ☐ Ventilate the patient
- ☐ Confirm proper tube position
- ☐ Insert nasogastric tube
- ☐ Obtain chest radiograph
- ☐ Administer postintubation drugs

Debriefing Team

- ☐ What went right
- ☐ What went wrong
- ☐ What to change next time
- ☐ Additional training needed
- ☐ Equipment issues
- ☐ Other things to discuss

device. Administer adequate sedation and neuromuscular relaxation as necessary. Place a nasogastric tube to decompress the stomach.

COMPLICATIONS

The complications associated with RSI are numerous (**Table 16-7**), ranging from minor airway trauma to cerebral anoxia and death. **The technique of RSI should be performed only by experienced Emergency Physicians. The availability of alternate invasive airway devices and techniques can often prevent complications if oral endotracheal intubation is unsuccessful.** A more complete discussion of the complications is contained in Chapter 18.

The procedure of RSI has many steps. It is sometimes easier to remember the 10 P's of RSI: plan, preparation (of drugs, equipment, and people), protect the cervical spine (if indicated), positioning (can be done after paralysis), preoxygenation, pretreatment (e.g., atropine, fentanyl, lidocaine), paralysis, protection (i.e., Sellick's maneuver), placement (endotracheal tube and confirmation of its position), and postintubation management (**Table 16-8**). A sample checklist and protocol can simplify the procedure and decrease the complication rate (**Tables 16-9 and 16-10**).

SUMMARY

Rapid sequence induction is the preferred method to secure an airway on an emergent basis and when there is a risk of aspiration of gastric contents. In experienced hands, it is a relatively safe procedure with few complications. The choice of pharmacologic agents used will vary by physician experience, physician preference, the clinical condition of the patient, and the pharmacology of the agents.

Delayed Sequence Intubation

Kevin J. Donnelly, Gennadiy Voronov, and Ned F. Nasr

INTRODUCTION

Delayed sequence intubation (DSI) is an alternative technique in optimization of preoxygenation for noncompliant patients with altered mental status. The technique is designed to improve preoxygenation by providing controlled sedation.¹ The current evidence consists of data from small studies of patients sedated with ketamine and successfully preoxygenated and intubated.¹⁻⁶ DSI evidence is based on a small series of cases. This technique can be successful for many patients, including those with asthma.

ANATOMY AND PATHOPHYSIOLOGY

DSI separates the administration of induction drugs from the administration of paralytic agents to allow preintubation oxygenation and denitrogenation of the patient.¹ It has been described as procedural analgesia and sedation (Chapter 159) for the procedure of preoxygenation and denitrogenation. Denitrogenation makes the functional residual capacity of the lungs to be filled with oxygen to provide an oxygen reservoir. Ketamine is used as the induction agent (Chapter 12). The ketamine allows the patient to maintain airway reflexes and spontaneous respiration. DSI allows a longer time for intubation, increases the apnea time, decreases the risk of gastric insufflation, and decreases the risk of aspiration. DSI may prevent peri-intubation acidosis, carbon dioxide elevations, cardiac arrest, hypotension, hypoxemia, morbidity, and mortality.¹ A bag-valve device is not used to ventilate the patient in DSI. This may result in a decreased gastric insufflation and the subsequent risk of aspiration.

INDICATIONS

The primary indication for DSI is to provide controlled sedation to achieve adequate preoxygenation and denitrogenation in the patient intolerant of desaturating (i.e., oxygen saturation < 93%) when emergent rapid sequence intubation (RSI) would be otherwise unsafe due to the risk of severe hypoxemia.¹ Some patients may not need to be intubated once the sedation has led to dramatic increases in oxygen saturation. Improved cooperation along with the adequate oxygen saturation levels may allow the Emergency Physician to observe the patient before immediately continuing to intubation. Safe and controlled endotracheal intubation is performed to secure the patient's airway once the oxygen reserve and saturation level have reached an

appropriate value. DSI allows essential procedures (e.g., nasogastric tube placement) to be performed prior to intubation.

CONTRAINDICATIONS

Contraindications include situations in which definitive airway control is needed in a non-spontaneously breathing patient. Patients who present with increased aspiration risk are not candidates for DSI. A relative contraindication is in the patient with hypertension, tachycardia, and increased intracranial pressure when the sympathomimetic effects of ketamine will be undesirable (Chapter 12). Contraindications to the administration of ketamine (Chapter 12) are contraindications to DSI. Patients under the influence of illicit substances or medications or with psychiatric disorders that cause delirium or hallucinations may experience additive effects with the administration of ketamine. Emergency Physicians with minimal to no experience with providing ketamine sedation should not provide DSI.

EQUIPMENT

The equipment required for DSI is the same as that for any intubation (Chapters 16 and 18). Difficult airway equipment should be readily available if the patient cannot be intubated (Chapter 14). This can include laryngeal mask airways (Chapter 26), a cricothyroidotomy tray (Chapter 32), a retrograde guidewire kit (Chapter 30), or a percutaneous transtracheal jet ventilation system (Chapter 31).

PATIENT PREPARATION

Provide supplemental oxygen via nasal cannula or nonrebreather mask. **Be prepared with the equipment, trained personnel, and monitoring systems before initiating DSI.** Apply a noninvasive blood pressure cuff, continuous pulse oximetry, and cardiac monitoring. Obtain intravenous (IV) access in two locations if possible. Use the intraosseous route if an IV cannot be obtained (Chapter 70).⁷ Flush the IV line and angiocatheter with sterile saline to ensure it is patent. Prepare suction and ensure it is working in case it is needed. Set the IV line to keep open with a saline bag. Safely secure the patient using restraints or extra personnel to avoid harm to the patient or others in the area. Consider administering an antisialagogue (e.g., atropine or glycopyrrolate) if time allows to decrease excessive oral and respiratory tract secretions. Evaluate the patient's airway and devise a detailed plan for the intubation following the RSI or DSI technique. Have additional ketamine and the medications for RSI prepared and drawn up at the bedside. Have difficult airway equipment at the bedside.

TECHNIQUE

Consider DSI in the patient with unsuccessful attempts at preoxygenation secondary to agitation, combative behavior, confusion, delirium, or any other state resulting in an oxygen saturation of less than 93%. The procedure is summarized in **Figure 17-1**. Administer 1 to 2 mg/kg of ketamine over 10 to 20 seconds.⁸ The slow intravenous push will result in a calmed and cooperative patient within 30 to 45 seconds. **Ketamine will not blunt the patient's respirations or airway reflexes.** Administer a second dose of 0.5 to 1.0 mg/kg of ketamine if the patient remains agitated and is not tolerating the preoxygenation. Place the patient in over 30° of head-up position for preoxygenation. The dissociative state produced by the ketamine will allow the application of preoxygenation.⁹

Preoxygenation can proceed with the use of a nonrebreather mask, nasal cannula, or, in some cases, noninvasive continuous positive airway pressure (Chapter 11) of 5 to 15 cmH₂O. Continue

preoxygenation for another 2 to 3 minutes once the patient reaches an oxygen saturation > 95%. Intubate the patient with or without paralytics while maintaining adequate oxygen saturation (Chapters 16 and 18). Neuromuscular blocking agents can be used for paralysis (Chapter 12).

PEDIATRIC CONSIDERATIONS

Sedation for the pediatric population requires expertise. The Emergency Physician handling the pediatric airway must be familiar with pediatric anatomy, medication dosage, and respiratory physiology.¹⁰ The noncompliant pediatric patient just before sedation is very similar to the agitated adult patient who does not tolerate preoxygenation.¹¹ The described technique of DSI for adults can be applied to children with appropriate weight-based dose adjustment of the medications. Intramuscular injection of ketamine is described but reserved for children without IV access due to the unpredictable time and depth of sedation. DSI has not been clinically studied in the pediatric population. Future studies and clinical trials have to confirm the effectiveness and safety of DSI in this group.

ALTERNATIVE TECHNIQUES

Dexmedetomidine is an alpha-2 agonist that provides sedation with no blunting of respiratory drive or airway reflexes.¹² A dose of 1 µg/kg administered over 10 minutes will lead to sedation. The use of dexmedetomidine will require a longer waiting period before most patients allow preoxygenation when compared with ketamine, which requires 30 to 45 seconds.¹³ Other agents include droperidol, etomidate, and fentanyl derivatives.^{1,14} These medications have not been adequately studied in the setting of DSI to make any recommendations.

ASSESSMENT

Monitor oxygen saturation levels, blood pressure, good chest rise and fall with ventilation, and adequate IV medication access. Evaluate the increase in oxygen saturation level with ketamine administration. **Confirm that endotracheal intubation is successful (Chapter 19).** This includes auscultation, fogging of the endotracheal tube with ventilation, and the presence of persistent end-tidal CO₂ (i.e., capnograph or a chemical colorimetric indicator).¹⁵

AFTERCARE

Some patients may not ultimately need to be intubated once the sedation has led to dramatic increases in oxygen saturation.¹ Improved cooperation along with the adequate oxygen saturation levels may allow the Emergency Physician to observe the patient before immediately continuing to intubation. The aftercare is the same as for any intubated patient (Chapters 16 and 18). Secure the endotracheal tube with tape or a commercially available device. Administer adequate sedation and neuromuscular relaxation as necessary. Monitor oxygen saturation levels and airway pressures.

COMPLICATIONS

Complications of DSI are rare and similar to those orotracheal intubation (Chapters 16 and 18).¹ DSI can lead to complications; thus, a rapid back-up plan is needed in case of an impediment. DSI goes against the technique described as RSI. The amount of time allowed for preoxygenation with sedation medication can lead to gastric contents entering the oropharynx and significant aspiration. Do not overlook the risk of pulmonary aspiration despite the use

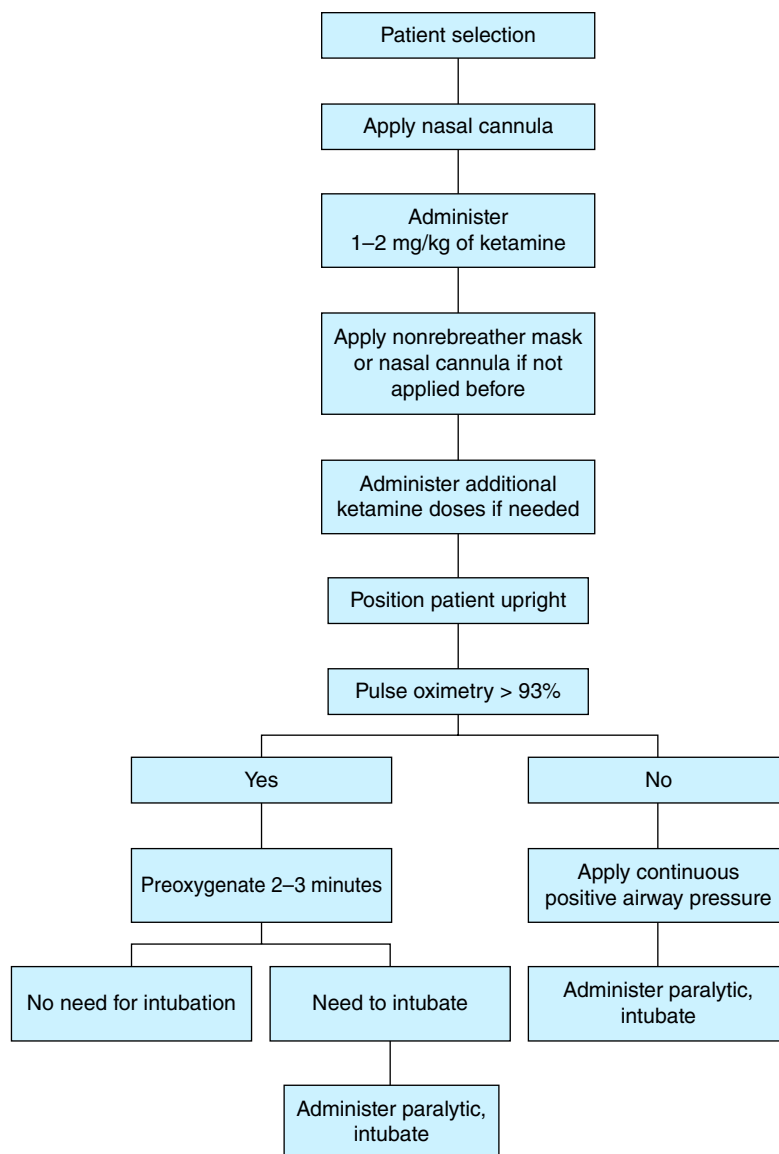

FIGURE 17-1. DSI algorithm.

of ketamine or dexmedetomidine to maintain spontaneous respirations and reflexes.¹⁶

Side effects of ketamine include excessive agitation, delirium, hallucinations, increased cardiac demand with tachycardia and hypertension, and increased airway secretions (Chapter 12). These side effects can lead to serious complications while attempting to sedate and intubate the patient. Obtaining a complete medical history and drug history before administering these drugs is crucial for safe outcomes.

SUMMARY

Effective preoxygenation and denitrogenation during the peri-intubation period allows the Emergency Physician to intubate the patient with adequate oxygen reserve and sufficient time before desaturation. Patients often arrive to the Emergency Department confused, combative, delirious, or uncooperative. These patients pose a great risk for desaturation and hypoxia during induction and intubation. The experienced and knowledgeable Emergency Physician can apply oxygen supplementation that is tolerated and effective. This rise in oxygen saturation and oxygen reserve volume in the alveoli can improve intubating conditions and overall patient oxygenation.

Orotracheal Intubation

Hyangwon Paek, Gennadiy Voronov, and Ned Nasr

INTRODUCTION

Airway control is the first and most critical action of the Emergency Physician. The “A” in the ABC’s demands that no other action may take place until the airway is secure. Endotracheal (ET) intubation inserts an artificial airway connecting the respiratory system to the outside world and provides definitive control of the airway. All methods of support can be applied once the ET tube is in place. Nothing can help the patient if the airway is not secure. ET intubation can be accomplished by a variety of methods. The method of choice will be dictated by physician preference and experience, the patient’s condition, and the available equipment. The most common method of ET intubation is orotracheal intubation. **There are no good alternatives to intubation when oxygenation and ventilation are threatened. All actions should be focused on the objectives of getting the ET tube placed quickly and in the right location.** The proper preparation, practice, and personnel can assure that the “nightmare airway” is an extremely rare event.¹

ANATOMY AND PATHOPHYSIOLOGY

The discussion of anatomy starts at the lips and travels inward to end at the right mainstem bronchus. Visualize the normal structures expected and match them with what is seen as you approach the patient. Distortion occurs from edema or trauma. Structures may be hidden by vomit or blood. Airway structures are viewed upside down from the position of standing over the head of the supine patient. The potential for disorientation is multiplied due to the upside-down view.

Begin at the face and move inward (**Figures 18-1 and 18-2**). The philtrum of the upper lip will be located at the 6 o’clock (i.e., bottom) position. Symmetrical swelling, carbon deposits, blistering, or signs of trauma to the lips can indicate that the inner anatomy of the airway may be altered and the intubation more difficult. Open the patient’s mouth and check the teeth for fractures, size, and the presence of removable dental devices. Large upper incisors (i.e., buck teeth) and/or limited jaw opening will make orotracheal intubation more difficult. The tongue hangs down from the floor of

FIGURE 18-1. Schematic representation of the airway. The patient is in the “sniffing” position.

the mandible and ends with the tip against the maxillary incisors (**Figure 18-2**). Visualize the tongue as a hanging oval of tissue with two “tips.” The first is the anterior tip of the tongue proper. The second is the posteriorly located epiglottis. The anatomic floor of this view is formed by the hard and soft palates, which end at the palatopharyngeal arch (**Figure 18-2**). The uvula is located inferiorly and in the midline. The palatoglossal arch and palatopharyngeal arch form twin vertical pillars that lie posterior to the molars of the upper teeth (**Figure 18-2**). All of these structures are potential sources of obstruction and must be evaluated for swelling, deformity, or trauma. The back wall is the posterior wall of the pharynx (**Figure 18-2**).

The airway bends 90° at the posterior wall of the pharynx to run almost parallel to the gurney. The root of the tongue and the

FIGURE 18-2. The oral structures as viewed from above the supine patient’s head.

FIGURE 18-3. The tongue and adjacent structures as viewed from above the supine patient's head.

lingual tonsils are located at the 12 o'clock position when visualized from the perspective of the top of the patient's head (**Figures 18-3 and 18-4**). The tongue continues into a blind pocket known as the vallecula. The vallecula is continuous with the epiglottis. The epiglottis hangs with its tip pointing downward. Directly behind and protected by the epiglottis is the entry to the remainder of the airway (**Figure 18-4**). The esophagus lies at the 6 o'clock position. The hypopharynx appears like the number "8" from the viewpoint of the intubator. The top half is the airway and the bottom half the esophagus (**Figure 18-4**).

Under the epiglottis is the larynx (**Figure 18-5**). The vocal cords are located in the midline and form an "A" shape, with its apex superior and toward the epiglottis. **Identifying the vocal cords is important since the visualization of the ET tube passing between**

the vocal cords is proof of a successful ET intubation. The arytenoid cartilages are paired structures (**Figure 18-5**). One lies at the posterior aspect of each vocal cord. The aryepiglottic folds are paired structures that span from the lateral edge of the epiglottis to the arytenoid cartilages (**Figure 18-5**). They contain the muscles that move the arytenoid cartilages and subsequently move (i.e., open and close) the vocal cords. The trachea bifurcates at the carina into the right and left mainstem bronchi. The cartilaginous tracheal rings are sometimes visible through the vocal cords.

INDICATIONS

Any threat to oxygenation and/or ventilation is a relative indication for orotracheal intubation. Remove the threat if it is simple and easily removed. **Orotacheal intubation is required if there is uncertainty that the patient's airway patency, respiratory drive, or oxygenation cannot be maintained without intervention. Time is of the essence. The decision to intubate early can make**

FIGURE 18-4. Structures of the hypopharynx as viewed from above the supine patient's head.

FIGURE 18-5. The structures of the glottis as viewed from above the supine patient's head.

the difference between a controlled, successful procedure and a chaotic, “crashing” nightmare. Orotracheal intubation can be performed to administer resuscitation medications, ensure a patent airway, deliver oxygen, isolate the airway, reduce the risk of aspiration of gastric or oral contents, suction the trachea, ventilate the patient, and apply positive-pressure ventilation. Other indications for orotracheal intubation include altered mental status, head injury requiring hyperventilation, hypoxemia, hypoventilation, apnea, lack of a gag reflex, shock, and unconsciousness.

CONTRAINDICATIONS

Orotracheal intubation is relatively contraindicated in patients who do not need it, who are likely to be injured by the procedure, or whose injuries make success unlikely. Spontaneous breathing with adequate ventilation and normal mental status may allow less invasive techniques such as continuous positive airway pressure (CPAP) in patients whose medical conditions are likely to respond quickly to interventions (e.g., cardiogenic pulmonary edema or pneumonitis).² Trauma patients with likely cervical spine injury or anterior neck wounds and severely immobile arthritis patients may be injured by the manipulation required during orotracheal intubation.³ Successful orotracheal intubation may be impossible with severe orofacial injuries, bleeding, deep airway obstruction, or gross deformity of the head and neck. A quickly changing obstruction (e.g., edema or an expanding hematoma) may require a surgical airway if orotracheal intubation is delayed. **Choose a surgical airway if the manipulation or time required for orotracheal intubation puts the patient at risk for spinal injury or hypoxia.**⁴ Orotracheal intubation should not be performed by individuals unfamiliar with the equipment and technique.

EQUIPMENT

- ET tubes, various sizes (Table 18-1)
- 10 mL syringe
- Water-soluble lubricant or anesthetic jelly
- Wire stylet, malleable type
- Laryngoscope handle
- Fresh batteries for the laryngoscope

TABLE 18-1 Oral ET Tube Sizes and Positioning Based on Patient Age

Patient's age	Size* (French)	Internal diameter (mm)	External diameter† (mm)	Distance inserted from lips (cm)
Premature	10	2.5	3.3	9–10
Full-term/newborn	12	3.0	4.0–4.2	11
1–6 months	14	3.5	4.7–4.8	11
6–12 months	16	4.0	5.3–5.6	12
1–2 years	18	4.5	6.0–6.3	13
3–4 years	20	5.0	6.7–7.0	14
5–6 years	22	5.5	7.3–7.6	15–16
7–8 years	24	6.0	8.0–8.2	16–17
9–10 years	26	6.5	8.7–9.3	17–18
11–13 years	28–30	7.0	9.3–10.0	18–20
Female ≥ 14 years	28–30	7.0	9.3–10.0	20–22
Male ≥ 14 years	32–34	8.0	10.7–11.3	22–24

- Resuscitation medicines
- Personnel (respiratory technician, medication nurse, in-line stabilization assistant, recorder)
- Medications (premedications, induction, anesthetics, paralytics) (Table 18-2)

Many institutions make their own intubating/airway kit. It contains all the commonly used equipment in a portable container or cart that can be moved wherever required in the Emergency Department. While differences will exist between institutions, the kit commonly includes the following: adult and pediatric laryngoscope handles, various sizes and types of laryngoscope blades, various sizes of oropharyngeal airways, various sizes of nasopharyngeal airways, tongue blades, malleable stylets, various sizes of ET tubes, syringes, tape, and commercially available devices to secure the ET tube. Some institutions may have a single kit or separate kits for adult and pediatric patients.

ET TUBES

The ET tube is a clear polyvinyl chloride disposable tube that is open on both ends (Figure 18-6).⁵ The proximal end contains a standard size 15 mm connector that will attach to the bag-valve device, a ventilator, and other sources of positive-pressure ventilation. The distal end is beveled. It has a perforation located approximately 0.5 to 0.75 cm from the tip and opposite the bevel. This perforation is known as the Murphy eye. Printed on the tube are the size, a radiopaque line to aid in radiographic visualization, and 1 cm incremental marks beginning at the tip. An inflatable cuff or balloon is positioned proximal to the Murphy eye. A pilot balloon with an inflation port to inflate the cuff hangs from the proximal third of the ET tube. An air-filled syringe attaches to the inflation port to inflate and deflate the cuff.

The ET tube cuff is a high-volume, low-pressure balloon. **The cuff is designed to accommodate a high volume of air before the intracuff pressure rises.** This is an extremely important feature. Intracuff pressure is transmitted to the delicate tracheal mucosa where it can cause pressure necrosis and ischemia.

The Parker Flex-Tip tracheal tube is curved, designed to facilitate rapid intubation, flexible, and nontraumatic, with a distal tip geometry that is different from a traditional ET tube (Parker Medical, Highlands Ranch, CO).⁶ The tube is designed to flex and slide past airway structures rather than getting caught and causing trauma to these structures. The tip of the Parker tube lies close to the stylet and

TABLE 18-2 Rapid Sequence Induction Medications for Specific Patient Profiles

Patient type	Premedication*	Induction and paralysis†
"Normal adult"	Rocuronium (0.06 mg/kg)	Etomidate (0.3 mg/kg) or propofol (1.5–2.5 mg/kg) and succinylcholine (2 mg/kg)
"Normal child"	Rocuronium (0.06 mg/kg) and atropine (0.02 mg/kg, min dose 0.1 mg)	Propofol (2–3 mg/kg) and succinylcholine (2–3 mg/kg)
Asthma, adult	Lidocaine (1.5 mg/kg) and glycopyrrolate (0.1–0.2 mg)	Ketamine (1–2 mg/kg) or propofol (1.5–2.5 mg/kg) and succinylcholine (2 mg/kg)
Asthma, child	Lidocaine (1.5 mg/kg) and atropine (0.02 mg, min 0.1 mg)	Ketamine (1–2 mg/kg) or propofol (2–3 mg/kg) and succinylcholine (2–3 mg/kg)
Head injury, adult	Rocuronium (0.06 mg/kg) and lidocaine (1.5 mg/kg)	Etomidate (0.3 mg/kg) or propofol (1.5–2.5 mg/kg) and succinylcholine (2 mg/kg)
Head injury, child	Rocuronium (0.06 mg/kg) and atropine (0.02 mg/kg, min 0.1 mg) and lidocaine (1.5 mg/kg)	Etomidate (0.3 mg/kg) or propofol (1–3 mg/kg) and succinylcholine (2 mg/kg)
Head injury, adult, hypotensive	Rocuronium (0.06 mg/kg) and lidocaine (1.5 mg/kg)	Etomidate (0.2 mg/kg) and succinylcholine (1.5 mg/kg)
Head injury, child, hypotensive	Rocuronium (0.06 mg/kg) and atropine (0.02 mg/kg, min 0.1 mg) and lidocaine (1.5 mg/kg)	Midazolam (0.05–0.2 mg/kg) or fentanyl (1–3 µg/kg) and etomidate (0.3 mg/kg) and succinylcholine (2 mg/kg)
Hyperkalemia or renal failure, adult	None	Etomidate (0.2 mg/kg) or propofol (1–2 mg/kg) and rocuronium (0.6 mg/kg) or vecuronium (0.01 mg/kg)
Hyperkalemia or renal failure, child	None	Etomidate (0.2 mg/kg) or propofol (1–2 mg/kg) and rocuronium (0.6 mg/kg) or vecuronium (0.01 mg/kg)
Status epilepticus, adult	None	Etomidate (0.3 mg/kg) or propofol (1.5–2.5 mg/kg) and succinylcholine (2 mg/kg)
Status epilepticus, child	None	Etomidate (0.3 mg/kg) or propofol (1–3 mg/kg) and succinylcholine (2–3 mg/kg)
Pregnancy	Aspiration prophylaxis: ranitidine (50 mg) and metoclopramide (10 mg) Rocuronium (0.06 mg/kg) and glycopyrrolate (0.1–0.2 mg)	Ketamine (1–2 mg/kg) or propofol (1.5–2.5 mg/kg) and succinylcholine (1 mg/kg)

*Given 3 minutes before intubating ($T = 3$).†Given simultaneously at the beginning of intubation ($T = 0$) and wait for 45 to 60 seconds for onset of paralysis.

minimizes this gap that could result in the ET tube getting caught. The Parker tube is available in many different styles.

The choice of ET tube size will vary based on the patient's age, anatomic anomalies, body habitus, and airway anatomy (**Table 18-1**). **The ET tube is sized based on the internal diameter (ID) measured in millimeters.** The size is printed onto the surface of the ET tube for reference. The sizes begin with 2.5 mm and increase in 0.5 mm increments. Some generalities hold true in most patients. Adult males usually require a size 7.5 to 8.0 cuffed ET tube. Adult females usually require a size 7.0 to 7.5 cuffed ET tube.

ET tube selection in children can be made by one of several methods. A Broselow tape will identify the proper size tube. Visually select a tube with an ID that matches the size of: the width of the nail of the patient's little finger, the width or diameter of the fifth finger, the diameter of the distal phalanx of the third finger, or the external nares luminal diameter. All of these visual methods will approximate the same size ET tube. The following formula may be used to confirm the uncuffed ET tube size: $(16 + \text{child's age in years})$

**FIGURE 18-6.** A variety of ET tubes. (Photo courtesy of Eric F. Reichman, PhD, MD.)

$\div 4$. Tables based on the child's age, length (e.g., Broselow tape), or weight may be used to estimate the proper ET tube size. An uncuffed ET tube was recommended to be used in children under 28 days of age to prevent the complications of subglottic and tracheal stenosis. Select and prepare a second ET tube that is one size smaller in case the patient's airway is smaller than expected.

Traditional teaching holds that cuffed ET tubes increase the risk of ischemic damage to the tracheal mucosa due to compression between the cuff and the cartilaginous rings. This results in the old mandate to use uncuffed ET tubes in children younger than 8 years of age. There have been numerous advances in modern ET tubes that are changing this orthodoxy.⁷ Some current guidelines recommend, but do not require, a cuffed ET tube for children older than 28 days of age. In the first 28 days of life, the cricoid narrowing functions as a cuff. Use of cuffed ET tubes in infants and neonates less than 28 days of age has been demonstrated to be safe.^{8–13} For children over 28 days of age, the cuffed ET tube is just as safe as an uncuffed ET tube.^{14,15} The high-volume, low-pressure cuffs found on new ET tubes allow the cuff to produce a seal at much lower pressures. The use of cuffed ET tubes is becoming more common in pediatric Intensive Care Units and Emergency Departments. Several studies have shown no increase in postintubation stridor or reintubation when cuffed ET tubes are used in controlled settings with regular cuff pressure monitoring.

Potential benefits in children from the use of cuffed ET tubes include some protection from aspiration, allowance of ventilation at higher pressures, maintenance of more consistent ventilatory parameters, and fewer changes of inappropriately sized ET tubes.¹⁶ Cuffed ET tube size can be calculated using the following equation: $(\text{age in years}/4) + 3$; cuffed ET tube size can also be determined by using an ET tube one-half size smaller than the calculated uncuffed ET tube size.^{17,18}

All ET tubes should be examined for defects before use. Attach a 10 mL syringe filled with air to the pilot balloon inflation port. Inject the air to inflate the cuff. The cuff should inflate symmetrically and have no air leak. Deflate the cuff completely. Leave the syringe attached to the pilot balloon in order to inflate the cuff after the ET tube has been inserted into a patient's airway. Discard any defective ET tube and prepare a new ET tube.

FIGURE 18-7. A variety of laryngoscope handles. (Photo courtesy of Eric F. Reichman, PhD, MD.)

LARYNGOSCOPES

The laryngoscope is a handheld device that is used to elevate the tongue and epiglottis to expose the glottis. **It is a device that is held in the left hand regardless of which hand of the user is dominant.** It consists of a handle (**Figure 18-7**) and a blade (**Figures 18-8 and 18-9**). The handle contains the battery for the light source. The distal end of the handle has a fitting where the handle connects to the blade. A transverse bar indicates where the indentation on the proximal blade attaches to the handle. There are many types of laryngoscope handles. They all have the same basic design and are available in a variety of diameters and lengths (**Figure 18-7**). Smaller diameter (i.e., thinner) laryngoscope handles may be better suited for use with the smaller sized pediatric laryngoscope blades. Shorter “stubby” laryngoscope handles may offer an advantage when proceeding with intubation of obese or barrel-chested patients, especially in cases where the neck cannot be manipulated. The shorter handle will not catch on the chest wall during attempts to place the laryngoscope blade in the patient’s mouth.

The laryngoscope blade may have a removable bulb that is attached to its distal third. A fiberoptic bundle within the blade transfers power from the handle to the bulb. Other laryngoscope blades only contain fiberoptic bundles which transmit light from

FIGURE 18-8. The Macintosh laryngoscope blades. (Photo courtesy of Eric F. Reichman, PhD, MD.)

FIGURE 18-9. The Miller laryngoscope blades. (Photo courtesy of Eric F. Reichman, PhD, MD.)

the light source located within the handle. The choice of the type and size of laryngoscope blade will vary with physician experience and preference. **The best blade is one that the intubator feels comfortable and confident using.** The curved Macintosh blade is most commonly used (**Figure 18-8**).¹⁹ It is the easier blade to use for those with little experience with orotracheal intubation. Many feel that it requires less forearm strength to use as compared to the straight blade. The large flange allows for easier control of the tongue, and the flat curved shape of the spatula fits the natural curve of the tongue. The straight Miller blade is often used in patients with a floppy epiglottis, large tongue, prominent incisors (i.e., buck teeth), or overriding teeth (**Figure 18-9**).²⁰ Children can be intubated with either a Macintosh or Miller blade.^{21,22}

The tip of the curved Macintosh blade fits into the vallecula and indirectly lifts the epiglottis to expose the vocal cords (Figure 18-10). A size 2 blade is used for children 3 to 6 years of

FIGURE 18-10. Use of the Macintosh blade. It is inserted into the vallecula to elevate the mandible, tongue, and epiglottis as a unit.

FIGURE 18-11. Use of the Miller blade. It is inserted below the epiglottis to elevate the mandible, tongue, and epiglottis as a unit.

age. A size 3 blade is used for children starting at about age 6, for women, and for small to average-size males. A size 4 blade is usually reserved for large males. The size 4 blade requires more power to lift the handle. This is because as the distance from the tip of the blade to the handle increases, the harder it becomes to lift the tongue and epiglottis as well as to maintain the blade straight. **Choosing the shortest blade that is long enough to reach the vallecula will allow the best intubation attempt.** The Macintosh Extended Flange (i.e., the English blade) has a spatula of the blade that is smooth and has an extended gentle curve. It is widely used because some contend that it allows better visualization due to the continuous natural curve of the spatula that is not present in the standard curved Macintosh blade.²³

The tip of the straight Miller blade goes directly under the epiglottis to lift it and the tongue to expose the vocal cords (Figure 18-11).¹⁹ A straight blade makes controlling the epiglottis and tongue easier than with a curved blade. It also makes visualization of the vocal cords easier due to its smaller flange profile. A size 0 blade is used for premature babies and neonates up to approximately 1 month of age. A size 1 blade is used for children from approximately 1 month of age to toddlers up to 2 years of age. A size 2 blade is used for children 3 to 6 years of age. Children between 6 and 12 years of age may require either a size 2 or 3 blade depending on their body size. A size 3 blade is used for adolescents, women, and average-size males. A size 4 blade is rarely used, and then primarily for large males. If one cannot remember the proper blade size, it can be determined based on patient anatomy.²⁴ Place the base of the blade, excluding the handle insertion block, at the level of the patient's upper incisor teeth. The tip of the blade should be located within 1 cm proximal or distal to the angle of the patient's mandible. Correct blade size allows for approximately 90% of first attempt intubations to be successful versus 57% if the blade is too small.²⁴

There are a wide variety of laryngoscope blades commercially available. They tend to be variations of the curved Macintosh or straight Miller blades (Figure 18-12). The McCoy blade is a curved blade with a hinged tip (Figure 18-12A). The tip can be flexed by depressing a lever on the laryngoscope handle. This flexion augments indirect elevation of the epiglottis by stretching the

hypoepiglottic ligament. The Flexiblade (Arco-Medic Ltd., Omer, Israel) laryngoscope also has a levering blade (Figure 18-12B). The extra lift provided by these blades may improve visualization of the vocal cords.^{25,26} The Propper Flip-Tip laryngoscope blade (Propper Manufacturing Co., Long Island, NY) has a lever that elevates its tip up to 90° to lift the epiglottis (Figure 18-12C). Other variations of the Macintosh blade include the incorporation of a variety of prism or mirror systems. These modifications allow for indirect visualization of otherwise obscured vocal cords. The Bel-scope (International Medical Inc., Burnsville, MN), Truvue EVO2 (Truphatek International Ltd., Netanya, Israel) (Figure 18-12D), Lee-Fiberview (Anesthesia Medical Specialties, Beaumont, CA), and Viewmax (Rusch, Duluth, GA) blades are examples of these types of modifications.

There have also been many variations of the straight laryngoscope blade. Today, the Miller is the most popular straight blade. Other variants include the Phillips (Figure 18-13) and Henderson blades. These modify components such as the cross section, the blade channel width, tip style, and light source placement. These modifications represent efforts to avoid such problems as dental trauma, laceration of the ET tube cuff, tongue displacement, tip trauma, and obscuration of the light source by secretions.

In addition to traditional metal laryngoscope blades, plastic single-use blades are also available (Figure 18-14). These single-use plastic blades were developed, in part, because of concerns regarding possible transmission of infectious agents by incompletely sterilized metallic blades. A study comparing plastic versus metallic Macintosh laryngoscope blades in 1177 patients found that metallic blades had higher first attempt intubation rates, had fewer cases of difficult intubation, and used alternative airway interventions less often than when intubation was attempted with a plastic blade.²⁷ Plastic blades cause less dental trauma when used on dental models.²⁸ The rates of dental trauma in patients when compared to metal blades are not known. The use of single-use disposable plastic blades cannot be recommended at this time unless circumstances do not allow proper cleaning of metallic laryngoscope blades.²⁹

STYLETS

The stylet is a semirigid piece of metal that is usually bendable (Figure 18-15 and Table 18-3). It is often plastic coated. It inserts into the lumen of the ET tube. It should be lubricated with water-soluble lubricant or anesthetic jelly prior to insertion into the ET tube. **The tip of the stylet should be 1 cm proximal to the tip of the ET tube to prevent injury to the patient's airway.** The ET tube, with a stylet, can be bent to maintain a specific shape. The stylet is used to facilitate passage of the ET tube through the vocal cords. It is commonly bent into a "hockey-stick" or "J" shape for most intubations. A greater curvature is often used for intubations when the larynx is "anterior," in difficult intubations, and in "blind" intubations.

A modification of the traditional stylet is the Parker Flex-It Directional Stylet (Parker Medical, Highlands Ranch, CO). This is a plastic articulating stylet that requires no prebending (Figure 18-15B). The stylet has a built-in gentle curve. It has a button on its proximal end that extends from the ET tube. When pushed with the thumb, it allows the curvature of the ET tube to be continuously adjusted during intubation attempts.

Another modification of the traditional stylet is the Rapid Positioning Intubation Stylet or RPiS (Airway Management Enterprises LLC, Wellesley, MA). The RPiS was designed for difficult airways when the vocal cords are seen but the ET tube does not bend to go into the airway (Figure 18-15C). It is a hand-controlled intubating stylet with a tip that can flex and retroflex. The RPiS can accommodate ET tubes with internal diameters between 6.0 and 9.0 mm.

FIGURE 18-13. The Phillips variation of the Miller blade.

FIGURE 18-14. An example of a plastic, single-use blade.

FORCEPS

The McGill forceps is the standard used by most institutions (**Figure 18-16A**). The forceps are used to introduce the ET tube into the patient's trachea from the hypopharynx under direct visualization. It is available in infant, child, and adult sizes. The forceps tips twin blades for gripping are offset with serrated tips. It is curved at an oblique angle between the handles and the blades to prevent the view of the patient's airway from being obscured. The ends of the blades are rounded to minimize trauma.

The Boedeker forceps (Karl Storz Endoscopy, El Segundo, CA) is an alternative to the McGill forceps (**Figure 18-16B**). It is also curved but does not put the working end into the view of the intubator.

The Tylke forceps (Rodinia LLC, Jupiter, FL) is a new device that is simple to use, safe, and an effective alternative to the McGill forceps (**Figure 18-16C**). It allows nasotracheal intubations 25% of the time and reduces the possibility of torn cuffs and vocal cord trauma. The circular tip of the Tylke forceps prevents losing control of the ET tube, without having to grip the ET tube firmly, and allows the aiming of the ET tube in the desired direction. The twist and bend of the Tylke forceps prevent the vocal cords from being visually obstructed and provide improved access to the trachea. It is available in three sizes (i.e., adult, adolescent, and child).

A

B

C

FIGURE 18-15. The intubating stylet. **A.** It may be bent into any required shape. When inserted into an ET tube, it will form the ET tube into the desired shape. The most common shapes are the “J” and the “hockey stick.” **B.** The Parker Medical Flex-It. **C.** The Rapid Positioning Intubating Stylet.

TABLE 18-3 Characteristics of Some Stylets Available in the Emergency Department

Name	Manufacturer	Comments
CoPilot VL Rigid Stylet	Magaw Medical	Reusable Fits ET tube ≥ 6.0 mm inner diameter
GlideRite Rigid Stylet	Verathon	Reusable Fits ET tube ≥ 6.0 mm inner diameter Matches GlideScope angulated blade
Muallem ET Tube Stylet	VBM Medizintechnik	Atraumatic soft Coude tip
Optishape Stylet	Teleflex	4 sizes Fits ET tube with inner diameter (mm) of 2.5–3.5, 4.0–5.5, 5.0–6.5, and 7.0–9.0
Rapid Positioning Intubating Stylet (RPIS)	Airway Management Enterprises	Atraumatic soft tip Tip allows 180° of flexion and retroflexion
Standard ET Tube Stylet	Various	Fits ET tube ≥ 6.0 mm inner diameter Malleable Single-use and disposable Available in multiple lengths and diameters
Truflex Flexible Stylet	Teleflex	30–60° lift of flexible tip Fits ET tube 6.5–8.5 mm inner diameter Adjustable stopper for different length ET tube

Use of the Tylke forceps is simple (**Figure 18-16D**). Insert the Tylke forceps into the mouth. Grab the ET tube either from the right side or slide it over the tip of the ET tube with the Tylke forceps vertical. Another method is to tilt the Tylke forceps left 90° to encircle the tube from the top and then return the Tylke forceps to a vertical position. Aim the Tylke forceps at the vocal cords and have an assistant advance the tube through the vocal cords and into the trachea. Pull the Tylke forceps back to the oropharynx while loosely wrapped around the tube. Rotate the hand to the right, open, and disengage the Tylke forceps. Carefully remove the Tylke forceps from the mouth.

PREPARATION

PHYSICIAN

Once the decision to intubate has been made, the Emergency Physician must use their training and experience to begin leading the team toward a successful intubation. Although the process must move quickly, the Emergency Physician must, by example, ensure a calm and orderly environment. Making the decision to intubate earlier allows the team to follow a shorter and easier time line. The Emergency Physician must visualize this time line and identify actions and potential problems before they occur. **A backup plan should also be available in case orotracheal intubation is impossible.** Any Emergency Department patient about to be intubated is a high priority, so do not be afraid to use resources liberally. Obtain assistants to help as soon as the decision to intubate is made.

PERSONNEL

Shortly before the procedure begins, assemble the entire team near the bed and go over “the game plan” calmly and quickly. All personnel involved with the procedure should be gloved, gowned, and masked. Eye protection should be worn by all personnel to protect against splash injury from blood and secretions. **Explicitly identify**

FIGURE 18-16. Forceps used to aid intubation. **A.** The McGill forceps. **B.** The Boedeker forceps. assistants and assign their roles early. Give instructions clearly and calmly before the procedure begins. It is helpful to write down medications and doses in the order that they will be given and to review them quickly with the medication nurse. A designated nurse should draw up, label, and administer the medications followed by a saline flush. It should be emphasized that during the procedure this will be a particular nurse's only role. The respiratory assistant has three important tasks: helping to ventilate the patient, applying cricoid pressure, and handing the ET tube to the intubator so that visual contact with the vocal cords is not lost. A third assistant should be explicitly instructed as to how and when the team leader would like the patient's neck secured if cervical spine immobilization is needed.

EQUIPMENT

The mnemonic **SOAPME** (Chapter 16 and **Table 16-8**) can be used to help review the equipment required for intubation (suction, oxygen, airway, pharmacology, monitoring, and equipment).³⁰ Check that the room is ready and all equipment is within arm's reach. Turn on the suction and the oxygen. Confirm that both systems work. Attach the suction tip and check to see whether there is a small finger hole in the barrel that must be covered for the suction to work. If so, close it with a piece of tape so that the suction is always on. This is not a concern if a Yankauer suction catheter is being used. Ensure that the suction tubing is long enough to reach the center of the bed. Place the suction catheter under the mattress to the right of the patient's head and within easy reach. Place the spare suction tip nearby. Set the oxygen flow regulator to 15 L/min. Apply a nonrebreather mask to the oxygen and the patient. Place the bag-valve device near the head of the bed and within easy reach. Confirm that the noninvasive blood pressure cuff, cardiac monitor, and pulse oximeter are working and attached to the patient. Confirm that the end-tidal CO₂ monitor is nearby and working.

If such a monitor is unavailable, a disposable in-line monitoring colorimetric device should be available. Ensure that the patient has at least one working intravenous line.

Assemble the intubation equipment. Place the proper size laryngoscope blade on the handle. Open the blade and confirm that the light works. Close the blade into the ready position, flat against the handle to keep the bulb cool and not drain the batteries. Take the ET tube and the backup smaller one and prepare them. Insert the 10 mL syringe into the inflation port of the pilot balloon for the ET tube cuff. Inject enough air to inflate the balloon. Deflate the balloon until it is completely flat against the ET tube if there is no leak. **Leave the syringe attached.** Liberally lubricate the stylet with water soluble lubricant. Insert the stylet into the ET tube until its tip is 1 cm proximal to the distal tip of the ET tube. Place a bend in the stylet as it enters the proximal end of the ET tube to keep the stylet from advancing. Bend the stylet-ET tube assembly into a curve roughly approximating a "hockey stick" or "J" (**Figure 18-15**). Lubricate the tip of the ET tube and the collapsed cuff. This prevents the ET tube from getting caught on the epiglottis and making its advancement through the vocal cords difficult. Place the assembly back into the ET tube package. Place the ET tubes, laryngoscope, backup laryngoscope handle and blades, oral airways, and tape on a tray within easy reach of the bed. Check the room lighting. Raise the bed to minimize excessive bending and better visualize the patient's airway.

PATIENT PREPARATION

If the patient is competent and awake, explain the procedure, clarify advance directives, and obtain consent. If time permits, a history is especially helpful. The mnemonic **AMPLE** can help to provide quick information on allergies, medications, past medical history, last meal, and events leading to the current problem. Evaluate the patient's airway (Chapter 16).³¹⁻³⁴

Confirm again that the appropriate monitoring sources are working and attached to the patient. Confirm adequate intravenous access. Place the patient, with a normal neck, in the “sniffing” position with the head extended at the atlantooccipital joint while the neck is relatively flexed.³⁵⁻³⁹ A folded towel under the occiput helps to gently raise and tilt the head back into the proper position (Figures 10-1, 18-1, and 18-17). **Correct positioning is probably the most important preparation of the patient.** Place the obese patient into the head-elevated position using a ramp or pile of sheets under their head and shoulders (Figure 10-2). This position facilitates spontaneous ventilation, mask ventilation, and laryngoscopy.⁴⁰⁻⁴² It also prolongs the patient’s oxygen saturation during and after rapid sequence induction.

Begin preoxygenation for 5 minutes before the procedure if the patient is breathing spontaneously and if time permits. Use a well-fitting nonrebreather mask with the oxygen flow regulator set at 15 L/min. This displaces nitrogen from the lungs and gives the patient a physiologic reservoir of oxygen for approximately 5 minutes while apneic. **Remember, 5 minutes of preoxygenation provides 5 minutes of protection.**⁴³ If bag-valve-mask ventilation is required, have an assistant apply posteriorly directed cricoid pressure to minimize gastric distention and decrease the chance of vomiting and aspiration. Have assistants ready to turn the patient onto their left side to minimize the risk of aspiration if vomiting occurs. Monitor the pulse oximeter to assure good oxygenation and ventilation. It should rise to the high 90s and remain there. If not, check the O₂ circuit from the wall to the patient and confirm that spontaneous breathing is still occurring.

TECHNIQUE

The evaluation and preparation for orotracheal intubation are complex and essential. The intubation will hopefully be quick and anticlimactic if the preparation is done well. Position the respiratory assistant to the right side near the patient’s head. The intubator should stand at the head of the bed. Adjust the bed to place the mattress level with the intubator’s umbilicus. Pull the bed away from the wall at least 2 feet and clear a “maneuvering space” of tubes, lines, and equipment to prevent distractions. The assistant should stand at the intubator’s left hip and be ready to remove the cervical collar and hold the patient’s neck in position if in-line cervical immobilization is needed.

Grasp the laryngoscope with the left hand. **It is a left-handed instrument regardless of the handedness of the intubator.** Pull it open and lock the blade onto the handle. Confirm that the light is functioning. The tip of the laryngoscope blade should be pointed toward the patient’s chin. Pass the prepared ET tube and suction catheter to the respiratory assistant, who will place them into your right hand when asked. This allows the intubator to maintain constant visual contact with the patient’s airway during the procedure.

Induction of anesthesia is the final preparation for orotracheal intubation. The choice of drug sequence is based on the physician’s experience and the patient’s condition (Table 18-2). A typical sequence begins with a defasciculating dose of a nondepolarizing neuromuscular blocking drug (Table 16-9). After 2 to 3 minutes, induce anesthesia with a sedative followed immediately by a paralytic agent (i.e., succinylcholine). Apply cricoid pressure. Once the patient’s muscles are relaxed, perform the intubation as described below. Please refer to Chapters 12 and 16 regarding the complete details of the pharmacology of the induction agents and rapid sequence intubation. **Some patients, especially the old and sick, may stop breathing earlier than anticipated. Be prepared to intubate before the expected time of drug onset.**

Observe the patient’s chest. Watch it rise. Note the time when chest rise stops. Place your right thumb on the patient’s jaw. Gently

pull down the lower lip and open the mouth. Reinspect the oral cavity. Remove any dentures or foreign bodies. Compare what you see with what you expect to see. Fix any problems as you go further into the airway. If blood or vomit is seen, ask for the suction catheter. **Apply the suction catheter without removing your gaze from the patient’s airway.** When done suctioning, hold the suction catheter up for the assistant to take.

INTUBATING WITH THE (CURVED) MACINTOSH BLADE

Firmly grasp the laryngoscope in the left hand (Figure 18-17A). Insert the tip of the Macintosh laryngoscope blade into the right side of the patient’s mouth. Smoothly advance the blade inward while keeping slight upward pressure against the tongue. Use the blade to trap and push the tongue to the left as the blade is simultaneously moved to the midline, “clearing a path” for your gaze. Keep the left wrist firm. **Use the forearm, wrist, and hand as a single unit and avoid bending or flexing the wrist. It is essential to move the patient’s tongue up and to the left.** The tongue will protect the mandibular teeth from being injured by the laryngoscope blade. It allows the laryngoscope blade to be moved away from the maxillary teeth. It also opens a path to visualize the patient’s airway.

When the blade has been inserted all the way, lift the patient’s airway up and forward exactly along the long axis of the laryngoscope handle, which is aimed toward a point directly above the patient’s chin (Figures 18-10, 18-11, and 18-17B). **Do not “cock” or “crank back” on the laryngoscope handle with your wrist or the back of the laryngoscope blade may break the patient’s incisors.** The epiglottis should be seen at the base of the tongue.

A variable amount of force is required to lift the mandible, tongue, and soft tissues to visualize the vocal cords. More force is required to visualize the vocal cords in patients who have a large tongue, are obese, have redundant pharyngeal soft tissue, or have trismus. Grasp the laryngoscope handle as close to its base as possible in these patients. **The lower grasp provides more control of the laryngoscope and a mechanical advantage to apply more force without dental trauma.**

Advance the tip of the laryngoscope blade into the vallecula—the space between the base of the tongue and the body of the epiglottis (Figures 18-10 and 18-17B). Lift the laryngoscope handle to raise the tongue, jaw, and epiglottis as a unit (Figure 18-10). Observe carefully as the epiglottis pivots upward and uncovers the glottis (Figure 18-5). The vocal cords should be visualized. Cricoid pressure (i.e., Sellick’s maneuver) may make intubation more difficult. If the cricoid pressure is adversely impacting the view, it should be relaxed or even removed.⁴⁴ The application of pressure by an assistant in the sequence of pressing the thyroid cartilage back, upward, rightward, and posteriorly can help bring the vocal cords into view when the intubator cannot apply more lifting force due to lack of strength or reluctance to lift the airway (e.g., a suspected neck injury).⁴⁵ **This is known as the BURP maneuver.**⁴⁶

Other anterior neck manipulation maneuvers known as optimal external laryngeal manipulation (OELM) and bimanual laryngoscopy may be applied.⁴⁷⁻⁴⁹ They differ from the BURP maneuver in that the intubator uses their right hand to manipulate the larynx into optimal position while simultaneously viewing the patient’s airway and controlling the laryngoscope with their left hand. An assistant then assumes control of the larynx, maintaining the same position as the intubator proceeds to insert the ET tube. Alternatively, to limit laryngeal movement during the hand off, the intubator can use their right hand to manipulate an assistant’s hand on the patient’s larynx.⁴⁹ When properly positioned, instruct the

FIGURE 18-17. Orotracheal intubation with the Macintosh blade. The patient is in the “sniffing” position. **A.** Proper positioning of the laryngoscope blade above the patient’s mouth. **B.** The blade is inserted into the vallecula. The handle is lifted anteriorly and inferiorly to elevate the mandible, tongue, and epiglottis (arrow) to visualize the glottis. **C.** The ET tube is inserted into the trachea until the cuff is below the vocal cords. **D.** The laryngoscope has been removed and the cuff inflated. **E.** The ET tube is secured.

assistant to keep their hand still while the intubator removes their hand off the assistant's hand. A third variation uses the assistant to manipulate the patient's larynx while the intubator verbally directs them.

When the vocal cords are visualized, instruct the assistant to pass the ET tube into your right hand. This allows you to keep a "visual lock" on the vocal cords. Insert the ET tube into the right side of the patient's mouth. Advance the ET tube so that the tip reaches the vocal cords without letting the body of the tube block the view. Continue to advance the ET tube through the vocal cords until the cuff passes through them and into the trachea (**Figure 18-17C**). Advance the tube an additional 2 to 3 cm. **The tip and cuff of the ET tube must be visualized passing through the vocal cords to assure placement in the trachea.**

The fit of the ET tube through the vocal cords always seems to be tight, even in larger patients. **A well-lubricated tip with the cuff completely collapsed is essential.** Rolling the tube gently between the thumb and index finger at the moment of insertion can also help pilot the tip between the vocal cords. Ask the assistant to pass the already prepared smaller ET tube if the first ET tube is too large or the vocal cord opening is narrow.

The average depth of insertion (in cm) of the ET tube starting from the patient's lips is listed in **Table 18-1**. It can also be calculated using one of the following formulas: ET tube ID (in mm) \times 3, (age in years \div 2) + 12 for patients over 2 years of age to a maximum of 18 years of age, or age + 10 for children less than 8 years of age.

Once the ET tube has been inserted, the intubator's right hand must hold the tube in place continuously until it is properly secured. The assistant should inflate the ET tube cuff with the attached 10 mL syringe of air (**Figure 18-17D**) and then remove the syringe and stylet. **The intubator must hold the ET tube firmly to make sure that it does not become dislodged when the stylet is removed.** The assistant should attach the end-tidal CO₂ monitor and the bag-valve device to the ET tube. Secure the ET tube in position in the right corner of the patient's mouth if symmetrical lung sounds are heard on auscultation and if the pulse oximetry and CO₂ monitoring appear appropriate (**Figure 18-17E**).

INTUBATING WITH THE (STRAIGHT) MILLER BLADE

Intubating with the straight blade is similar to the curved blade with a few differences. **Insert the laryngoscope blade gradually.** Insert the tip directly under and slightly beyond the epiglottis if it is seen. Lift the epiglottis and airway by raising the left hand along the long axis of the laryngoscope handle toward a point above the patient's chin (**Figure 18-11**). **The tip of the laryngoscope blade is in the esophagus if neither the epiglottis nor the vocal cords are seen.** Locate the airway by lifting as above while slowly withdrawing the laryngoscope blade. As the tip slides back, it will "catch" the epiglottis and the airway should "fall down" into view. The BURP or OELM maneuver may now be applied if necessary. Some physicians use a variation of this to localize the epiglottis by inserting the blade deeply, lifting the soft tissue, withdrawing the laryngoscope blade while feeling for the "give" as the epiglottis tip falls off of the retreating blade, and then readvancing a small distance to "scoop up" the epiglottis and expose the airway. However, when using the Miller blade on pediatric patients, a careful insertion and advancing of the laryngoscope blade is required, while constantly visualizing from the surface of tongue to the vallecula or epiglottis. Some have advocated for the technique of advancing deep into the esophagus and then visualizing laryngeal structure during withdrawal. We contend that this should be avoided because this practice may cause laryngeal trauma with the blade tip damaging the arytenoid

cartilage or aryepiglottic fold, as well as increasing the incidence of esophageal intubation.¹⁶ It may be difficult to distinguish the glottic opening from the esophagus in the pediatric patient.

ASSESSMENT

Simple commonsense methods will quickly and accurately assess ET tube placement. The confirmation of ET intubation is briefly described in this section. Please refer to Chapter 19 for a more detailed discussion. **The assessment must be made quickly! An ET tube in the wrong place (i.e., the esophagus) is as quickly dangerous as a properly placed one is lifesaving. Was the ET tube visualized passing through the "A frame" of the vocal cords? This is the most important assessment.** If it was directly visualized being placed and continuously held in place, it is properly positioned. Is the pulse oximeter reading in the high 90s and steady or rising? Is the CO₂ monitoring appropriate?⁵⁰ Be familiar with the monitor in your institution. Electronic monitors will show a respiratory waveform and a numerical value.⁵¹ In-line colorimetric devices connected between the ET tube and the respiratory circuit will change color with inspiration and expiration to indicate the flow of CO₂ past the device.⁵¹

Evaluate the patient. Symmetrical upper chest rise without increasing abdominal size suggests proper placement. Persistent "fogging" or condensation inside the ET tube with each breath for at least six ventilations will also confirm proper placement. Auscultate lateral to the nipples for strong and symmetrical breath sounds during positive-pressure breaths. Avoid auscultating in the midline, where "normal" breath sounds can be heard from a misplaced ET tube in the esophagus. Auscultate at the lateral apices and bases of the lungs. Auscultate over the epigastrium. Correct placement will give strong, symmetrical breath sounds except in the epigastrium. **Assume incorrect ET tube placement if epigastric sounds are strongest, if "gurgling" is heard, or if vocalization is heard.** Breath sounds that are asymmetrical and stronger on the right indicate a right mainstem intubation. Deflate the cuff and gently withdraw the ET tube in 1 cm increments while auscultating. Continue to withdraw the ET tube until equal breath sounds are heard. Secure the tube and reinflate the cuff.

Obtain a chest radiograph after clinically confirming the placement of the ET tube.⁵² The tip of the radiopaque stripe of the ET tube should end over the third or fourth thoracic vertebra and 3 to 4 cm above the carina of the trachea. Always inspect the radiograph for any signs of a pneumomediastinum, pneumothorax, or hemothorax.

Clinical assessment of the ET tubes position should take less than 15 seconds. If you are unsure of the ET tube position, leave the first tube in place while applying cricoid pressure. Look to see if the ET tube is passing between the vocal cords if the patient's pulse oximetry reading is in the mid- to high 90s. Alternatively, the ET tube can be removed and intubation reattempted. If the pulse oximetry is low, remove the ET tube and ventilate the patient with a bag-valve-mask device for 30 to 60 seconds to allow the pulse oximetry to rise into the high 90s before making a second attempt at intubation. Some physicians prefer to leave the misplaced ET tube in place.⁵³ Leaving the first tube might seem to complicate subsequent intubation attempts but can serve to vent gastric vomit out of the oropharynx as well as to locate the esophageal entrance during the next attempt at direct visualization of the airway.⁵⁴

As long as ventilation is possible with the bag-valve-mask device and pulse oximetry can be maintained above 92% (i.e., PO₂ = 60 mmHg), two or three attempts can be made at orotracheal intubation.⁵⁵⁻⁵⁷ **Stop the intubation attempt and ventilate the patient for 30 to 60 seconds if 30 seconds of time have elapsed or pulse**

oximetry falls to 92% or below. In training programs, the third attempt should be made by the most skilled person available. Three failed attempts define a “failed airway” and call for rescue intubation by an alternative method. **Any patient in whom bag-valve-mask ventilation becomes impossible must be given a surgical airway.**

AFTERCARE

The ET tube must be secured to prevent it from migrating distally or proximally. The traditional method of wrapping tape around the ET tube and then around the patient’s head is rarely used today. If used properly, tape functions just as well or better than commercially available ET tube holders.⁵⁸ A variety of disposable, relatively inexpensive, and single patient use ET tube holders are commercially available. They are easy to apply, adjust, and reposition if necessary. The basic unit is a nonlatex plastic ET tube holder that positions over the patient’s mouth, a cushioned neckband, and Velcro closures for a snug fit. There are many variations of this basic unit.

A nasogastric tube or orogastric tube is often placed after orotracheal intubation to remove air, fluid, and gastric juices from the stomach. This tube must also be secured. It is either taped to the patient’s face or to the ET tube to prevent it from migrating distally or proximally. One specific ET tube holder is a novel device that deserves mention. The Intubix (Intubix LLC, Houston, TX) is an ET tube holder with a built-in bite guard and orogastric tube side port (Figure 18-18). It allows the blind passage of the orogastric tube through the side port as well as securing it in position.

Postintubation management should include pain control, sedation, and paralysis if indicated. The patient should be sedated and possibly paralyzed depending on the situation, so they do not fight the ET tube and extubate themselves. **The patient should never be paralyzed and not sedated so they are aware and but unable to respond.⁵⁹ This is considered cruel.** Administer an opioid analgesic as required for pain control. The patient may require repeated bolus dosing of these medications or a continuous infusion for analgesia, sedation, and/or paralysis depending on their condition.

COMPLICATIONS

HYPOXEMIA, MULTIPLE ATTEMPTS, AND MISPLACED ET TUBES

Hypoxia is the most destructive complication. It often results from prolonged intubation attempts, with or without proper preoxygenation, and unrecognized misplaced ET tubes. Without adequate oxygenation, irreversible brain injury begins to occur within 2 to 3 minutes. Hypoxia can result in cardiac arrhythmias.

Neonates and infants desaturate quicker than adults for many reasons. Their metabolic rate is twice that of an adult. The lungs are a smaller volume and have less alveoli. The neonate and infant minute ventilation is dependent on the rapid respiratory rate. The amount of dead space is greater in the neonate and infant than in the adult. The chest wall is more compliant and easily collapses. Hypoxia of the neonate and infant brain causes bradycardia. Cardiac output is rate dependent.

The complications of orotracheal intubation increase with more than one attempt.⁶⁰ Complications were found to increase with over two intubation attempts.^{61,62} Some studies confirmed that complications increase when more than one intubation attempt is made.⁶³⁻⁶⁶ Regardless of one or two attempts, the authors agree that complications increase when more attempts at intubation are made. Orotracheal intubation should be accomplished by the most skilled person available.

An unrecognized esophageal intubation will result in significant morbidity and mortality. After intubation, the proper ET tube placement should be confirmed by auscultation, chest rise, fogging in the ET tube, end-tidal CO₂ monitoring, and chest radiography. **Any manipulation or movement of the ET tube or the patient’s upper body (i.e., head, neck, and torso) should be followed by an assessment of the ET tube position.** It can easily become dislodged and migrate into the hypopharynx and esophagus. Other methods to confirm ET tube placement include inserting a fiberoptic bronchoscope through the ET tube and visualizing the tracheal rings and carina (Chapter 28) or inserting a

A

B

FIGURE 18-18. The Intubix ET tube holder. **A.** The unit. **B.** The unit with an ET tube and an orogastric tube attached.

lighted stylet and following the illumination into the trachea (Chapter 24).

The cuff of the ET tube can be malpositioned in the airway. Mainstem intubation can be detected on physical examination and chest radiography. The ET tube cuff can be located between the vocal cords. This is visualized on the chest radiograph, and the ET tube is easily advanced. The cuff can be located above the vocal cords with its tip at the vocal cords. The ET tube softens with the patient's body heat over time, and simple advancement might be impeded. The cuff and tip of the ET tube can be above the vocal cords (i.e., a complete extubation). Advancement can result in esophageal intubation.

POSTINTUBATION HYPOTENSION OR HEMODYNAMIC COLLAPSE

Orotracheal intubation may precipitate cardiac arrest, cardiac arrhythmias, or hypotension in patients with comorbidities or underlying heart disease. Cardiac arrest after intubation is associated with a poor outcome.⁶⁷ Consider resuscitating the patient before intubation if time allows.⁶⁸ Hypotension or cardiac dysrhythmias before intubation can result in postintubation cardiac arrest.⁶⁹⁻⁷³ Interventions for hypotension include intravenous (IV) fluids, vasopressor infusion, press-dose vasopressors, and checking to ensure the patient is oxygenated.

The mnemonic **DOPES** can be used to troubleshoot. It stands for displacement of the ET tube, obstruction of the ET tube, a pneumothorax, equipment failure, and breath stacking. A displaced ET tube may be in the esophagus, right mainstem, or oropharynx. Check the ET tube and reintubate if required. Obstruction is usually due to mucous plugs or biting of the ET tube. This is relieved with suctioning or sedation, respectively. Equipment failure refers to all of the equipment from the wall air sources and to the patient. Use a bag-valve device attached to the ET tube to ventilate the patient while a second person checks and replaces the equipment. Finally, the stacking of breaths can result in gas trapping, high plateau and peak pressures, and incomplete gas return. Disconnect the breathing line and allow the patient to fully exhale.

Bradycardia can be produced by pharyngeal manipulation. It may be especially pronounced in children because of their higher vagal tone. Pretreatment with atropine (0.02 mg/kg with a minimum dose of 0.15 mg) in children under 6 years of age can avoid this. It will also serve to decrease airway secretions.

Increased intracranial pressure can occur as a result of the direct laryngoscopy. The exact cause of this transient rise is unknown. Lidocaine has been postulated as being of benefit in blunting this but is so far unproven. A dose of 1.5 to 2.0 mg/kg IV may be used as a premedication if time allows and the patient's condition warrants its use.

MECHANICAL COMPLICATIONS

Direct mechanical complications from the laryngoscope include lacerations of the lips, trauma to the pharyngeal wall, broken teeth, or dentures that may be aspirated and require later removal.⁷⁴ Vomiting can cause subsequent chemical and bacterial pneumonitis. A pneumothorax is a rarely seen complication of laryngoscopy. It is more often associated with positive-pressure ventilation. Laryngoscopy may cause apnea, bronchospasm, and/or laryngospasm due to prolonged stimulation of the pharynx.

Laryngospasm may result from insertion of the laryngoscope blade or attempts to advance the ET tube through the vocal cords.⁷⁵ This occurs more often in patients who are awake, semiconscious, not paralyzed, and not anesthetized. It is sometimes preceded by high-pitched inspiratory stridor followed by complete airway

obstruction. It can occur without any warning. Laryngospasm should be suspected in an airway obstruction. It is characterized by the inability to manually ventilate the patient, loss of end-tidal CO₂, no breath sounds, no chest wall movement, and no stridor. Laryngospasm can lead to bradycardia, cardiac arrhythmias, end-organ injury, hypoxia, and death.

Laryngospasm may be prevented by the application of nebulized lidocaine, topical anesthetic spray, transtracheal injection of lidocaine, or laryngeal nerve blocks.⁷⁶ **Remove the laryngoscope and begin positive-pressure ventilation if laryngospasm occurs during intubation. Positive-pressure ventilation through a face mask will often overcome the laryngospasm.⁷⁵ Inward and anterior pressure applied to the mandible at Larson's point or the laryngospasm notch can break the laryngospasm. Consider paralyzing the patient immediately with succinylcholine or performing a surgical airway if the laryngospasm is not relieved.⁷⁵**

The ET tube and stylet can be a source of mechanical complications.⁷⁷⁻⁸⁰ A sore throat is a common and self-resolving nuisance. Uvular necrosis occurs when the uvula is compressed between the ET tube and palate. This rare complication is self-limited and often heals within 2 weeks. Treatment includes antihistamines, steroids, and possibly antibiotics. The stylet protruding from the distal end of the ET tube can cause soft tissue contusions and lacerations, perforation of the vocal cords, hemorrhage into the airway, and perforation of the trachea.⁸¹ **Proper stylet placement with its tip within the ET tube will prevent these complications.** ET tube cuff overinflation can result in mucosal sluffing, pressure necrosis, and hemorrhage. Tracheal rupture is a rare but life-threatening complication.^{79,80} It may be due to cuff overinflation, a protruding stylet, intubation using more rigid and less pliable stylets, pushing through a weakness or defect, or multiple intubation attempts. The complications associated with cuff overinflation can be prevented by using seldom used manometry.

AIR LEAKS

A "leak" of air out from the patient's mouth or nose during ventilation signifies a mechanical problem with the ET tube. The ET tube must be removed and replaced if the cuff is damaged. Check the position of the ET tube by direct laryngoscopy. The ET tube will not secure the airway properly if the cuff is located between or above the vocal cords. Deflate the cuff, advance it through the vocal cords, and reinflate the cuff. There may be a leak in the pilot balloon or its tubing if the cuff slowly deflates. Reinflate the cuff and apply a hemostat to the tubing attached to the pilot balloon or attach a closed stopcock to the inflation port.

ASPIRATION

The risk of aspiration increases in patients with difficult airways or full stomachs. This includes obese and pregnant patients. The use of an awake ET intubation or rapid sequence intubation with cricoid pressure may minimize the risk of aspiration. **A properly placed ET tube with the cuff inflated will decrease, but not totally eliminate, the risk of aspiration.**

THE UTILITY OF SELICK'S MANEUVER

The use of cricoid pressure was introduced in 1774 to prevent gastric distention during artificial ventilation of drowning victims.⁸² Sellick reintroduced the application of cricoid pressure in 1961.⁸³ Cricoid pressure theoretically causes an occlusion of the upper esophagus by trapping it between the cricoid cartilage and the vertebral bodies. It has since been used on a daily basis for rapid sequence intubation by Anesthesiologists and Emergency Physicians. This maneuver

was thought to prevent regurgitation and gastric insufflation during positive-pressure ventilation.^{84,85} The application of cricoid pressure was later termed “Sellick’s maneuver.”

Sellick’s original publications were small observational studies self-reporting on his technique. These studies were not blinded, controlled, or randomized. Several subsequent studies determined the amount of force required to occlude the esophagus on cadavers and patients. It is not practical or possible to measure the cricoid force applied during clinical care in the Emergency Department.

Multiple studies have found adverse effects associated with Sellick’s maneuver.^{47,84,86-97} It can worsen the laryngoscopic view of the airway. Other complications include bruising, airway obstruction, cricoid cartilage fracture, goiter hemorrhage, subconjunctival hemorrhage, and esophageal rupture.⁹⁵ Cricoid pressure decreases lower esophageal sphincter tone and may explain in part the cases of pulmonary aspiration prior to intubation.

Sellick’s maneuver is considered by some to be the standard of care.⁹⁸ Very little evidence supports its use to prevent aspiration.⁸⁸⁻⁹⁰ No studies have shown that the application of Sellick’s maneuver improves patient outcomes.^{85,99} Even Anesthesiologists do not agree on its use.¹⁰⁰ **This does not mean Sellick’s maneuver should not be performed!** It may be of benefit to prevent aspiration, especially in the Emergency Department where patients are considered to have “full stomachs.” Slowly release cricoid pressure in an attempt to improve ventilation or airway visualization if intubation or ventilation is difficult using Sellick’s maneuver.¹⁰¹

ENDOTRACHEAL CUFF PRESSURE

Inflation of the ET tube cuff is required to adequately ventilate a patient without an air leak, provide positive-pressure ventilation, and prevent aspiration. There can be a fine line between proper cuff inflation and overinflation.^{102,103} One of the goals of any procedure is to prevent complications from the procedure itself. Underinflation of the ET tube cuff can result in aspiration, extubation, and inadequate ventilation. Overinflation of the ET tube cuff can result in bloody phlegm, cough, dysphagia, hemorrhage, hoarseness,

mucosal necrosis, mucosal sloughing, nerve palsy, subsequent tracheal stenosis, tracheoesophageal fistula, tracheal rupture, tracheal wall damage, and tracheitis. **Physicians have traditionally palpated the pilot balloon to estimate cuff pressure and prevent any complications from overinflation. This method is not accurate.**^{104,105}

Measurement of the cuff pressure is simple, quick, and inexpensive. It should be considered whenever a patient is intubated.^{102,106-108} Cuff pressure should be measured if an intubated patient is moved.^{108,109} **Be careful because connecting a manometer can lower the cuff pressure.**¹¹⁰ Cuff pressure should be measured if a patient is transported by air because the cuff pressure changes at elevated altitudes.^{108,111-114} A pressure of up to 30 cmH₂O provides an adequate seal without compromising mucosal blood flow and lowers the risk of subsequent subglottic stenosis.¹¹⁵ Tracheal mucosal blood flow shows a decline at 30 cmH₂O, and is completely blocked at 45 to 50 cmH₂O.¹¹⁶ An ET tube cuff pressure manometer is needed to measure these pressures accurately.

There are numerous methods to quickly assess cuff pressure. **Palpation is not accurate and should not be used.** The simplest method is to use a manometer. These devices (Cufflator, Posey Corp., Pasadena, CA, or Rusch Endotest, Teleflex Medical, Research Triangle Park, NC) allow the simultaneous inflation of the cuff while monitoring the cuff pressure on a dial (**Figures 18-19A and B**). These devices function similarly to those used to inflate a car tire. While simple to use, they can be cumbersome due to their shape and weight. An in-line device that attached to the cuff inflation port is available (PressureEasy Cuff Pressure Controller, Smiths-Medical, Dublin, OH). The device has an indicator window that signals when the cuff pressure is maintained between 20 and 30 cmH₂O (**Figure 18-19C**). A third novel device is the Pressure Alert Endotracheal Tube. This device is not yet commercially available. It incorporates a “pop up” button into the pilot balloon that alerts the user when the cuff pressure is too high. Automated cuff pressure devices are available. These include the Pressure Eyes (formerly known as the Pyton, Bay State Anesthesia, Bristol, CT), the IntelliCuff (Hamilton Medical, Reno, NV), and the Cuff Sentry (Outcome Solutions, Mocksville, NC) (**Figures 18-19D through F**).

SUMMARY

Orotracheal intubation is both common and lifesaving. It is the primary and preferred method of airway management. Every Emergency Physician must master this skill. With proper preparation, definitive control of the airway can be obtained. This assures that patients can be oxygenated and ventilated when they cannot do this on their own. Good team leadership skills are nearly as important as physical dexterity and assure an orderly and quick procedure. Rapid patient assessment is important to prevent complications. If orotracheal intubation is unsuccessful, another form of intubation or a surgical airway should be performed.

Confirmation of Endotracheal Intubation

Tarlan Hedayati

INTRODUCTION

This chapter will review the various methods used to confirm appropriate endotracheal (ET) intubation. **Direct visualization of the ET tube passing through the vocal cords is the preferred method for the initial assessment of a properly placed airway.** This is not always feasible. Rates for incorrect ET tube placement have been noted to be up to 25%.^{1,2} **The verification of correct ET tube placement is as important or more important than the intubation procedure. Lack of proper confirmation of ET tube placement has the potential for serious patient harm and catastrophic outcomes if unrecognized and uncorrected.**³⁻⁵

For over 20 years, there has been ongoing research and development to improve upon the basic techniques of physical examination confirmation of ET intubation. Physical examination with auscultation has been found to be inadequately sensitive (94%) and specific (83%) as an independent method for confirmation of correct ET tube placement.⁶

This chapter discusses the use of physical examination findings, esophageal detection devices (e.g., syringe and bulb), carbon dioxide (CO₂) detection devices (i.e., qualitative detector and continuous quantitative monitor), and imaging techniques (i.e., radiography and ultrasound). Each method is described for a patient with normal anatomy and the absence of any pathology (e.g., chest or neck trauma). Certain patient conditions or pathology may affect the accuracy of some methods. **No single method is universally or completely reliable. The confirmation of ET intubation requires a multiple method approach.** This multiple method approach to confirmation of ET intubation is now the accepted practice according to the American College of Emergency Physicians (ACEP) Board of Directors policy statement as of January 2016.⁷

PHYSICAL EXAMINATION

The use of physical examination methods has been the mainstay for the initial evaluation of proper ET tube placement. Direct visualization of the ET tube insertion through the vocal cords and into the trachea is the first method to confirm proper ET tube placement. Direct postintubation visualization of the ET tube using laryngoscopy or bronchoscopy and noting tracheal rings past the end of the ET tube is the next best method of assessing correct ET tube placement.

Secondary methods for confirmation of ET intubation are an absolute requirement. Auscultate the chest and abdomen to assess for delivery of air to the lungs via either a bag-valve device or a mechanical ventilator (Figure 19-1). First auscultate over the epigastrium to assess for the absence or presence of sounds in the stomach. **The presence of an enlarging abdomen or audible air inflation into the stomach with each positive-pressure ventilation may be the initial sign of an esophageal intubation.** The next auscultation points are located at the chest wall lateral to the nipples. Auscultate bilaterally from top to bottom for the presence and equality of breath sounds. **Avoid auscultating over the central portion of the chest. This may lead to the misinterpretation of the transmission of esophageal or gastric inflation.**⁸ These sounds may mimic breath sounds and lead to failure in detecting an esophageal intubation.

The final note pertaining to auscultation involves equality of breath sounds. The anatomy of the left and right mainstem bronchi

FIGURE 19-1. The order of auscultation after intubation to confirm ET tube placement begins at the epigastrium (1) listening for absence of air sounds, then down both sides of the chest wall, just lateral to the nipple line (2–4).

allows for a preferential right mainstem bronchial intubation when the ET tube is placed too deep. Insertion in centimeters to a depth three times the diameter size of the ET tube (e.g., 21 cm for a 7.0 mm size ET tube) at the level of the incisor teeth generally is preferred. This will place the ET tube approximately 3 to 4 cm above the carina in an adult.⁹ Deflate the ET tube cuff if breath sounds are heard better on the right side and gradually withdraw the ET tube in 1 cm increments until equal bilateral breath sounds are auscultated. This will prevent complications from hyperinflation of the ventilated lung, inadequate ventilation and oxygenation, and pulmonary edema in the nonventilated lung.¹⁰ Please refer to Chapter 18 for a more complete discussion of ET tube size, insertion depth, and placement for adults and children.

The next assessment involves visualizing the chest wall and ET tube characteristics with each breath. **Unequal or a lack of chest rise and fall with each instilled breath may indicate a misplaced ET tube in a mainstem bronchus or the esophagus, respectively.** Condensation and/or fogging in the ET tube with each breath has been used frequently in the past to confirm proper ET tube placement. This has been proven to be an unreliable source of confirmation.¹¹ **Use fogging in the ET tube in conjunction with auscultation and visualization of bilateral chest wall movement.** The presence of vomit in the ET tube may be a sign of aspiration or esophageal intubation.

The final postintubation physical assessment is an evaluation of oxygenation via skin signs and, more reliably, pulse oximetry. Cyanosis and a down-trending oxygen saturation on the pulse oximeter are delayed findings. The patient may experience significant hypoxemia before cyanosis or a significant drop in the pulse oximetry appears. **Do not rely upon cyanosis and pulse oximetry as a first-line assessment to confirm proper ET tube placement.**

ESOPHAGEAL DETECTOR DEVICES

Esophageal manometer devices use the structural differences between the trachea and esophagus in determining correct ET tube placement. The semicircular tracheal cartilaginous rings provide a constant open passage for the flow of air. The tubular esophagus with its lack of a luminal support structure collapses and prevents movement of air when suction is applied.¹² The two types of ET tube confirmation devices that rely on this anatomic variance are the syringe and the manometer or bulb methods (Figures 19-2 and 19-3).

The syringe method relies on a gradual and constant retraction of the plunger while its tip is attached to the proximal end of

FIGURE 19-2. Examples of the bulb and syringe esophageal detector device. (Photo courtesy of WolfTory Medical, Salt Lake City, UT.)

the ET tube using a manufactured connector (**Figure 19-3**).¹³ The plunger will draw back easily and without resistance if the ET tube is correctly placed in the trachea (**Figure 19-3A**). The volume of aspirated air should be greater than 30 mL in less than 4 seconds.¹⁴ Resistance when drawing back the plunger is seen when the distal end of the ET tube is incorrectly placed in the esophagus (**Figure 19-3B**). **An airtight seal must be created between the syringe and ET tube to prevent any air leak that would lead to a false-positive test and result in the incorrect assumption that the ET tube is in the trachea.**

The manometer or bulb method relies on the collapse of the esophageal wall. Compress the bulb to remove any air it contains. Firmly and securely apply the bulb to the proximal end of the ET tube while still compressing the bulb. Release compression on the bulb. The ET tube is presumably in the trachea if the bulb inflates fully and easily. The ET tube is presumably in the esophagus if the bulb does not inflate fully and easily.

There are numerous circumstances in which an esophageal detector device has repeatedly failed to identify an improperly placed ET tube.¹²⁻¹⁷ Most notably is after bag-valve-mask ventilations in the absence of cricoid pressure. The stomach and esophagus can inflate with air and allow for easy flow of air into the device simulating air flow from the airway. The device may fail to detect a misplaced ET tube when the distal end of the ET tube is just above the vocal cords. There is no resistance to airflow when the distal end of the ET tube is above the vocal cords and the bulb or syringe device easily fills with air.

This method has been shown to falsely identify an esophageal intubation when the ET tube is placed into a mainstem bronchus or the tip of the ET tube is pressed against the tracheal wall. The subsequent resistance to back flow of air into the syringe or bulb mimics that of the collapsed wall of the esophagus. Withdraw the ET tube 1 cm and attempt using the esophageal detector device again if this occurs. Repositioning will continue to result in resistance to aspiration or bulb inflation if the ET tube is in the esophagus. The presence of heavy or thick pulmonary secretions or fluid in the lungs can plug the airways and reduce the flow of air into the syringe or bulb.¹⁵ Use care not to rapidly aspirate and potentially draw the tracheal mucosa into the ET tube yielding a false-negative result due to obstruction.¹⁴ The posterior trachea lacks cartilage and may collapse into the trachea in obese patients and prevent the flow of air.¹⁶⁻¹⁹

Consider the limitations of esophageal detection devices and use them as an adjunct to other methods as they can provide a rapid and

FIGURE 19-3. Using the syringe esophageal detector device. **A.** Correct placement of the ET tube in the trachea allows for aspiration of air. **B.** Placement of the ET tube in the esophagus will result in resistance to aspiration due to collapse of the esophageal wall.

inexpensive method for confirming ET tube placement.²⁰⁻²² This is especially evident in the patient with cardiac arrest, circulatory collapse, hypotension, or a pulmonary embolism where other devices are limited.²¹

CARBON DIOXIDE DETECTORS AND CAPNOGRAPHY

End-tidal carbon dioxide (ETCO₂) detection as a means for confirming proper ET intubation has been studied and recently confirmed to be the “most accurate” method.²³ The premise of ETCO₂ detection devices requires the presence of exhaled CO₂ passing through and exiting the ET tube. Adequate circulation is required for CO₂ to be produced and transported from the lung parenchyma. The accuracy of this method relies on its use in the noncirculatory collapsed and noncardiac arrest patient. ETCO₂ detection using qualitative or quantitative methods approaches 100% sensitivity and specificity in the patient with an inflated cuffed ET tube and spontaneous circulation. Nearly every case of a false-negative detection of a correct ET tube placement (i.e., correct ET tube placement in the absence of ETCO₂ detection) has been discovered in the cardiac arrest patient.^{18,19,24-28}

ETCO₂ detection devices can be used qualitatively as a one-time spot check using a colorimetric detector or monitored continuously via capnography. Both are used in a similar fashion and are in-line devices that have two connectors. One connector attaches to the proximal end of the ET tube and the other attaches to the oxygen delivery device (i.e., bag-valve device or mechanical ventilator tubing).

The colorimetric ETCO₂ detector uses a piece of pH-sensitive material that lies beneath a clear plastic window. The presence of CO₂ flowing through the device, typically using six manual breaths as the maximum number needed and the minimum amount to clear any gastric CO₂, causes a color change from purple to yellow that then changes back to purple in the absence of CO₂ (Figure 19-4). The minimum concentration of ETCO₂ required for a color change is 0.5%. Literature has brought into question whether newborns and children produce sufficient quantities of ETCO₂ for accurate detection using this method.

Capnography, or continuous quantitative graphical demonstration of ETCO₂ detection, involves placement of an infrared detector in-line between the end of the ET tube and the oxygen delivery device (i.e., bag-valve device or ventilator tubing). The infrared detector is then connected with a cable to an electronic monitor that interprets the reading and generates a waveform representation of the ETCO₂ levels. One of the advantages of this method over the qualitative approach is the ongoing monitoring of CO₂ production.

FIGURE 19-4. Colorimetric ETCO₂ detectors before (left) and after (right) exposure to exhaled CO₂. Note the change in color of the pH paper from purple to yellow when exposed to CO₂.

This allows a continuous assessment of the airway and ventilation as well as the overall quality of resuscitative efforts with some determination of outcome.⁶ Capnography is recommended to be used on all patients for confirming ET intubation and monitoring ventilation.²⁹⁻³²

The main disadvantage of CO₂ detectors for confirmation of ET intubation is false-negative results (e.g., airflow obstruction, cardio-pulmonary arrests, hypotension and other poor perfusion states, low-amplitude waveforms with low CO₂ emission, the presence of secretions on the device, and pulmonary embolism). Sensitivities approach 100% in the non-cardiac arrest patient with adequate cardiac output and pulmonary flow and 76% for patients in cardiac arrest for ruling out esophageal intubation in patients of all ages.³³⁻³⁵

A false-positive result may lead the Emergency Physician to believe the airway is secure if the distal end of the ET tube is located just above the vocal cords in the hypopharynx. The device may detect adequate levels of CO₂ without a properly secured and definitive airway in the trachea. False-positive results from an improperly placed ET tube may occur when the device is used a short time after the patient has consumed a carbonated beverage. The device cannot differentiate between gastric and pulmonary CO₂ sources.

The universal presence of capnography is not yet a reality. Its utility in most circumstances with few exceptions is undeniable. The colorimetric ETCO₂ detector is as equally reliable as capnography. It is a disposable, rapid, less expensive, and more widely available means to assess proper ET tube placement in the non-cardiac arrest patient.²³

RADIOGRAPHY

The lack of availability of radiographs or ultrasonography is far less of an issue.³⁶ These methods are unique in that they rely on anatomic relationships for confirmation of ET tube placement. Radiographs and ultrasonography may be particularly useful in the cardiac arrest patient.

The main utility for radiographic confirmation of ET intubation lies in its ability to detect whether the ET tube is placed too deeply into the trachea (Figure 19-5).³⁷ Locating the end of the ET tube approximately 4 cm above the carina may prevent some of the complications associated with a right mainstem intubation. The postintubation chest radiograph can assist in identifying any complications that may have resulted during the intubation (e.g., aspiration, a pneumomediastinum, a pneumothorax, or tracheal injuries). **The postintubation chest radiograph does little to distinguish between esophageal versus tracheal intubation. The delay in obtaining a radiograph to confirm ET tube placement puts the patient at significant risk.**

ULTRASONOGRAPHY

The use of ultrasound (US) in the Emergency Department has gained significant popularity in the diagnosis of various diseases and pathology. US is readily available, can be used at the bedside, and uses no ionizing radiation. US can identify conditions before and after intubation (e.g., pneumothorax or tracheal injury). It can be used during intubation to see the ET passing the vocal cords. US is used after intubation to confirm the presence of the ET tube in the trachea and its lack of residing in the right mainstem bronchus.

There are multiple methods for using US guidance to assess for proper ET tube placement.³⁸⁻⁴⁷ Practice in advance of needing US to become familiar with the US anatomy of the airway (Figure 19-6).⁴⁸ Table 19-1 notes some of the definitions related to airway US and the confirmation of intubation. The trachea is an air-mucosal interface with posterior reverberation or comet tail artifact (Figure 19-6D).

FIGURE 19-5. Chest radiographs after intubation. **A.** The ET tube is in the trachea and above the carina. **B.** The ET tube is in the right mainstem bronchus.

Two common methods of confirming proper ET tube placement are described below. The benefits of these two methods is that ventilation is not required for ET tube placement confirmation. There is no risk of inflating the stomach or its resultant emesis and aspiration of gastric contents in the case of an accidental esophageal intubation. A meta-analysis of transtracheal US accuracy in confirmation of ET intubation had a pooled sensitivity and specificity of 98%.⁴⁹

The first method uses a 7 to 10 MHz, high-frequency linear US transducer. Place the US transducer horizontally at the level of the suprasternal notch (**Figure 19-7**). A properly placed ET tube in the trachea will demonstrate shadowing of the ET tube posteriorly (i.e., the “bullet sign”) without direct visualization of the esophagus (**Figures 19-8A, 19-9, and 19-10A**). The trachea appears similarly to the previously described image, but the esophagus will be directly visualized to the left of the trachea (i.e., the “double track

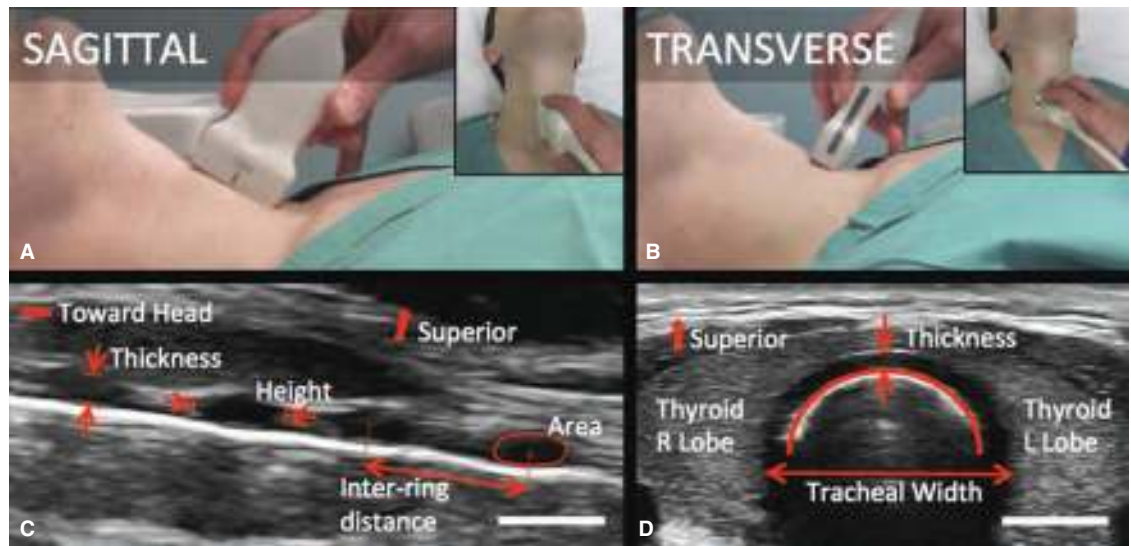

FIGURE 19-6. US of the trachea using a linear transducer. **A.** Positioning of the transducer vertically. **B.** The labeled US image visualized in part A. **C.** Positioning of the transducer horizontally. **D.** The labeled US image visualized in part C. (Used with permission from reference 48.)

TABLE 19-1 Definitions of Terms Used When US Is Performed for Intubation	
Terms	Definition
Bullet Sign	A properly placed ET tube in the trachea will demonstrate shadowing of the ET tube posteriorly
Double-tract sign	An esophageal intubation is considered if there are two air-mucosal interfaces visible, both having comet tail artifacts
Enhanced tracheal posterior shadow	An ET is considered if there is one air-mucosal interface visible with comet tail artifacts and enhanced posterior shadowing
Lung sliding sign	Pleural movement of the parietal and visceral pleura on chest US
Snowstorm sign	US image through the cricothyroid membrane with correct ET tube positioning
Triangular sign	Change in vocal cord shape when the ET tube passes them

sign”) with posterior shadowing due to the presence of the ET tube in the esophagus (**Figures 19-8B and 19-10B**). A small, prospective, randomized, controlled study found 100% sensitivity and 100% specificity in the accuracy of US as a method to confirm ET tube placement.⁵⁰

FIGURE 19-7. US transducer placement horizontally just above the sternal notch.

The second technique uses similar methodology over the cricothyroid membrane. Place the US transducer longitudinally over the cricothyroid membrane to identify the hyperechoic anterior and posterior laryngeal walls (**Figure 19-11**). The appearance of

FIGURE 19-8. Ultrasound images at the level of the sternal notch to confirm proper ET tube placement. **A.** Endotracheal intubation. The signature double echo of the plastic ET tube can be seen in the airway or trachea. (C, carotid artery, IJ, internal jugular vein, T, thyroid gland.) **B.** Esophageal intubation. The ET tube (arrow) is in the esophagus. It is positioned deep and lateral to the airway. (Ultrasound images courtesy of Sam Hsu, MD.)

FIGURE 19-9. US image of an ET intubation with the transducer placed horizontally just above the sternal notch. (Photo courtesy of Ultrasound Section, Emory University Department of Emergency Medicine.)

a “snowstorm” pattern between the two lines indicates correct ET tube placement (**Figure 19-12**).⁵¹

Foreign bodies are often hyperechoic and appear bright white on US. One study looked at using US to confirm ET tube placement with and without a stylet within the ET tube.⁵² The investigators hypothesized that the addition of a stylet would increase the sensitivity and specificity of identifying correct ET tube placement by adding an extra hyperechoic shadow to those of the ET tube. The use of a stylet did not improve US localization of the ET tube within the trachea.⁵²

US of the chest wall has been studied as a method of confirming ET tube placement.⁵³⁻⁵⁵ This method does require ventilation of the patient and uses the visceral-parietal pleural interface of the lungs to confirm inflation of the lung. Apply the US probe to the anterior-superior chest wall. Orient the US transducer vertically over the second and third ribs in the midclavicular line. The visceral and parietal pleural interface can be seen and appreciated as the so-called “sliding lung sign” (**Figure 19-13**). The hyperechoic interface will be seen moving back and forth with each respiration.⁵³⁻⁵⁵ Lung sliding can be used with other methods to confirm ET intubation.⁵⁶

US can be used to see the ET tube pass through the vocal cords (**Figure 19-14**).⁵⁶ Place the US transducer transversely and visualize the vocal cords (**Figure 19-14A**). View the triangular vocal

FIGURE 19-11. US transducer placement longitudinal or vertically over the cricothyroid membrane.

The *dashed arrows* demonstrate echogenic bands moving side-to-side with ventilations. The asterisks (*) identify the ribs. (Ultrasound image courtesy of Sam Hsu, MD.)

cords turn to a curved shape with the ET tube in the trachea (**Figure 19-14B**). This method is hard to perform as the vocal cords are thin and difficult to visualize using US.

TRACHEAL TUBE INTRODUCERS

The tracheal tube introducer (TTI) or gum elastic bougie has long been used to intubate in difficult conditions (Chapter 22). The TTI is a flexible rod-like device whose distal end is slightly angled. It is inserted through the patient’s vocal cords with the angled tip facing anteriorly during direct laryngoscopy. It is then advanced into the trachea. Advancement of the TTI causes the tip to slide along

the anterior tracheal cartilage rings. A “click” is palpable as the tip crosses each tracheal ring. The TTI will eventually stop or “hang up” as it passes into smaller bronchi. The ET tube is then advanced over the TTI and into the trachea.

Intubate the patient. Insert the lubricated TTI into the ET tube with the angled tip facing anteriorly. Advance the TTI through the ET tube. The tip will catch on each tracheal ring and “click” to verify proper ET tube position. The lack of any “clicks” or “hang up” suggests an esophageal intubation. This method is not 100% perfect like all other methods of confirming ET intubation.⁵⁷ Use the TTI in conjunction with other methods to confirm intubation.

DOCUMENTATION

Physicians are poor at documentation of ET tube confirmation.⁵ **Confirmation of the ET tube in the airway is critical.** This should be documented in the medical record. Document the location of the ET tube using positive or negative results and the corrective actions if taken. The lack of documentation can be the result of just not being written down in the busy Emergency Department, or it may not have been performed. This can be and is incorporated into some templates.

The documentation serves many purposes. The primary reason it is done is to document the medical care received and any decisions made. It provides information to consultants and others involved with the care of the patient. It is used for quality assurance and continuous quality improvement. The documentation is later used for billing and in medical malpractice cases to provide defenses.

SUMMARY

Insertion of an ET tube always requires verification of its proper placement. No one tool or technique is sufficient for any or all situations. The best method to confirm proper ET tube placement involves using multiple methods, keeping limitations in mind, and performing ongoing repeat assessments. Any change in a patient’s

A

B

FIGURE 19-14. US images through the cricothyroid membrane. **A.** The vocal cords are triangular shaped without the ET tube. **B.** The vocal cords are round with the correct positioning of the ET tube. (Used with permission from reference 56.)

clinical condition requires reverification that the ET tube is still properly positioned. The ongoing research and development of improved methods note the critical importance of rapid and accurate confirmation of ET intubation.

Video Assisted Orotracheal Intubation Devices

Pholaphat Charles Inboriboon and Curtis Blake Buchanan

INTRODUCTION

Direct laryngoscopy or the direct laryngoscope (both referred to as DL) was introduced in 1895 by Alfred Kirstein. Physicians have since developed instruments to improve visualization of the larynx while limiting tissue trauma. The Macintosh and Miller laryngoscope blades were developed in the 1940s and have been the primary tool for endotracheal (ET) intubation.¹ They have been effectively used for most ET intubations. There are limitations to their ability to allow direct visualization of the glottis and surrounding structures. Numerous adjuncts have been developed to assist in ET intubation.¹

The development of video laryngoscopy or the video laryngoscope (both referred to as VL) marks a new era in airway management (Tables 20-1 and 20-2).²⁻⁴ Traditional DL requires alignment of the oral, pharyngeal, and laryngeal axes to visualize the glottis (Chapter 9). It is not always possible to align these three axes with mechanical manipulation. **The major advantage of VL is that it does not require the Emergency Physician to align the three airway axes, reducing the need for manipulation and potential traumatic forces on the airway.**⁵ VL provides a superior view of the glottis when compared to traditional DL. The eye of the VL camera is within centimeters of the glottis and provides a wider angle of vision than the 15° of traditional DL. The video monitor magnifies the view of the airway, making structures easier to visualize. The American Society of Anesthesiologists recommends having VL available as a tool for their Difficult Airway Algorithm.⁶ This chapter reviews a representative number of device types currently available and used in Emergency Departments (Table 20-3). A recent study reviews commonly used VLs (Table 20-4).^{7,8}

PENTAX AIRWAY SCOPE

The Pentax Airway Scope (Pentax Medical Co., Montvale, NJ), known as the Pentax AWS or the AWS, is a rigid VL (Figure 20-1). It incorporates the blade, camera, and an ET tube targeting mechanism into one device. It is designed for prehospital, Emergency Department, and Operating Room use.^{9,10}

TABLE 20-1 The Advantages of Video Laryngoscopy

Alignment of oral, pharyngeal, and laryngeal axes not needed
Appropriate for prehospital, Emergency Department, and in-hospital use
Can be viewed by others
Cricoid pressure not needed
Decreased dental trauma with less lifting
Decreased esophageal intubation
Decreased use of bougies
Decreased use of external manipulation
High resolution
Improved first-pass success
Improved laryngeal view (Cormack-Lehane grades 1 and 2)
Less soft tissue lifting compared to DL
Minimal image distortion
Minimal cervical spine movement
Rescue device after failed DL
Sniffing position not needed
Teach airway anatomy
Teach DL
Use in known or suspected difficult airways
Use in morbidly obese
Use in "routine" intubation
VL-guided ET tube exchange

INDICATIONS AND CONTRAINDICATIONS

The AWS can be used for elective and emergent intubations. Patients with their head and neck immobilized can benefit from intubation with this device. It provides better visualization of the glottis, decreased cervical movement, and a higher success rate compared with traditional DL.^{11,12} Intubation with the AWS produces less airway stimulation than either the Glidescope or traditional laryngoscopes, thus minimizing the hemodynamic changes associated with intubation.^{12,13} There are no contraindications to using the AWS.

EQUIPMENT

The AWS incorporates an imaging system and a targeting system into one portable tool. It is ergonomically designed to minimize tissue trauma. Its use does not require the alignment of the three airway axes. The imaging system provides an illuminated 90° field of view in the original AWS-S100L model and 80° field of view in the AWS-S200. The S200 is lighter weight.⁹ The AWS produces better glottic visualization than traditional DL.¹⁴ The external shell is composed of water-resistant plastic, making it suitable for prehospital and Emergency Department use.

TABLE 20-2 The Disadvantages of Video Laryngoscopy

Adequate mouth opening required
Cost
Different device characteristics
Difficulty passing ET tube despite good airway view
Few comparisons between devices
Increased success in those familiar with device
Injury during ET tube advancement at blind spot
Learning curve with each device
Maintenance
Many different models available
May take longer to intubate than DL
Mucosal trauma
Skills required

TABLE 20-3 Some of the Available Video Intubation Devices and Their Characteristics

Name	Manufacturer	Comments
Airtraq Avant	Prodol Meditec	Disposable blade and eyecups Fits ET tube (ETT) sizes 6.0–7.5 and 7.0–8.5 inner diameter Guiding channel for ETT Low-temperature light source May be used in magnetic resonance imaging (MRI) Optional camera Partly disposable Regular and small adult versions
Airtraq SP	Prodol Meditec	Fits ETT sizes 2.5–3.5, 4.0–5.5, 6.0–7.5, and 7.0–8.5 inner diameter Fully disposable Low-temperature light source May be used in MRI No guiding channel Regular and small adult, pediatric, and infant versions Six color-coded sizes
Berci-Kaplan DCI Video Laryngoscope	Karl Storz Endoscopy	80° field of view from blades Large size of system Numerous blades available (Miller 0, 1, 4; MAC 2–4, Doerges, and D-blade) Requires components (monitor, light source, control unit) System with interchangeable laryngoscope blades Uses multiple airway devices
Clarus Video System	Clarus Medical LLC	4.0 inch color LCD screen Can be used as lighted stylet Malleable stylet Optional oxygen port Optional tube stop USB connection attaches to monitor or recording device Uses batteries
ClearVue Video Laryngoscope	Infinium Medical	3.5 inch color monitor 66° field of view 2 megapixel camera Anti-shatter screen Disposable and reusable models
C-MAC Pocket Monitor	Karl Storz Endoscopy	2.4 inch monitor that folds and moves in several directions Numerous blades available (Miller 0–1; MAC 2–4, S-blade, & D-blade) Rechargeable battery Works in sunlight Waterproof
C-MAC Video Laryngoscope	Karl Storz Endoscopy	7 inch color monitor 80° field of view from blades Built-in memory card Numerous blades available (Miller 0–1; MAC 2–4, S-blade, and D-blade)
CoPilot VL	Magaw Medical	Adult sizes 3 and 4 C-shaped channel for a bougie Rechargeable battery
Glidescope Advanced Video Laryngoscope (Glidescope AVL)	Verathon Inc.	Color monitor Light, impact resistant, and portable Numerous blades available (4 reusable blade sizes and 6 disposable blade sizes) Real-time video recording Reusable and single-use blades
Glidescope Ranger and Glidescope Ranger Single-use Video Laryngoscopes	Verathon Inc.	Built to military specifications Compact, rugged, and portable Rechargeable battery Reusable blade sizes 3 and 4 Single-use blade sizes 0–4
Glidescope Titanium	Verathon Inc.	6.4 inch color monitor Compatible with Glidescope AVL pediatric blades Durable and lightweight titanium Low-profile blade designs Numerous blades available (4 reusable, LoPro angled 3 and 4, MAC 3 and 4) Real-time video recording Reusable

TABLE 20-3 Some of the Available Video Intubation Devices and Their Characteristics (*Continued*)

Name	Manufacturer	Comments
Intubrite Video Laryngoscope	Intubrite LLC	3.5 inch color monitor 2 models available Records images and video Removable SD card Use in adults and children
King Vision aBlade Video Laryngoscope	Ambu USA	2.4 inch screen Attaches to an external display Battery powered (3 AAA) Channeled and nonchanneled blades Fits ETT sizes 6.0–8.5 inner diameter in channeled blade One size corresponds to MAC 3 Reusable video adapter EMS version available
McGrath MAC Enhanced Direct Laryngoscope	Physio-Control Inc.	Flat screen monitor on handle Numerous blades disposable available (2, 3, 4, X3) Screen displays battery usage Uses MAC-shaped blades
McGrath Series 5	Physio-Control Inc.	Blade adjusts to many sizes (adult and pediatric) Blade separates from handle Flat screen monitor on handle
Pentax AWS	Pentax Medical Co.	Single-use disposable MAC-shaped blade 2 models 4 blade sizes (neonate, pediatric, standard adult, thin adult) Alcohol or Cidex sterilization Disposable blades Micro USB port Video output to monitor
TotalTrack VLM Video Laryngoscope Mask	Medcom Flow	2.5 inch color screen 2 adult versions for ET tubes 6.0–8.5 Allows gastric and laryngeal aspiration Ideal for prehospital use Inserts from any intubator position Only mask currently available Output jacks SD slot
TruView PCD Video Laryngoscope	Teleflex	5.5 inch monitor Adult and pediatric models Records images and video Soft-feel handles
UE Scope	UE Medical Devices	2.5 inch monitor rotates and tilts Can be used on neonates through adults Designed for anterior airways Disposable and reusable models Rechargeable battery
Venner APA Video Laryngoscope	Venner Medical Intl.	3.5 inch monitor attached to reusable handle Attaches to external monitor Numerous blades disposable available (MAC 3 and 4, difficult airway blade)
VividTrac	Vivid Medical Inc.	Adult and pediatric versions Adult and pediatric sizes Attaches to computer or monitor with USB port Channeled blade Fits ETT sizes 4.0–6.0 and 6.0–8.5 inner diameter

The body is an integrated 12 cm long cable attached to a charge-coupled device camera, and both models have a 2.4 inch full-color LCD monitor (**Figure 20-1**). The monitor is hinged and allows a 0° to 120° angle for optimal viewing on the original S100L. The S200 is a fixed monitor on top of the device. The monitor screen incorporates a target symbol used to facilitate intubation. External monitoring and recording can be used with the external micro USB output with both devices. The device is battery operated using two AA alkaline batteries for 1 hour of continuous operation.

The PBLADE is a plastic, single-use, disposable, and transparent laryngoscope blade that attaches to the body of the AWS (**Figure 20-1**). It is designed to follow the natural curvature of the upper airway and minimize the need for manipulation of the three airway axes. The blade is composed of Lexan plastic that resists fogging, but not to the extent of the Glidescope antifogging mechanism.¹⁵ The PBLADE comes in four styles (i.e., standard adult blade, thin adult blade for micrognathia or bases where the oral opening is limited, pediatric blade, and neonate blade). The fiberoptic cable

and CMOS camera rest inside the cavity of the PBLADE. An ET tube is loaded into a track located on the right side of the blade. It accommodates a size 6.0 to 8.5 ET tube. Intubation is performed without the use of a stylet through the guided track. Suctioning can be performed under direct visualization with a 4.0 mm (i.e., 12 Fr) or smaller suction catheter inserted through the blade's suction port.

PREPARATION

Prepare and check the AWS before each use. Turn on the device. The video image and target symbol should appear on the monitor. The power lamp below the monitor should illuminate. Immediately replace the batteries if the monitor displays a flickering battery image. Check the light source. Place a hand below the tip of the AWS to ensure that it is illuminating. **Do not look directly at the light source.**

Attach the PBLADE to the AWS. Loosen the lock ring on the scope by rotating it in a leftward direction. **Align the triangular marks on the PBLADE and on the AWS body to ensure proper positioning prior to connection.** Insert the flexible fiberoptic tube through the scope insertion port on the blade. Realign the triangular marks. Keep the connector ring pressed in the direction of the scope body and push in the connector of the PBLADE. Release the connector ring. Confirm that the PBLADE is firmly attached and that the tip of the AWS comes into close contact with the scope window. Secure the connection by turning the lock ring in the rightward direction.

Load the ET tube. Liberally lubricate the ET tube with a water-soluble lubricant. Insert the ET tube by sliding it along the ET tube guide groove. Insert the ET tube by sliding it along the ET tube guide groove. Fix the ET tube onto the hooks located on the proximal end of the PBLADE. Adjust the ET tube so that the tip is aligned with the inferior edge of the PBLADE tip (**Figure 20-1**). Apply medical-grade antifogging to the outside of the PBLADE's scope window.

FIGURE 20-1. The Pentax AWS. **A.** AWS-S100L. **B.** AWS-S200 and PBLADES. (Photos courtesy of Pentax Medical Co., Montvale, NJ.)

TECHNIQUE

Gently insert the PBLADE into the patient's mouth as when performing DL. Insert it along the right side of the mouth. Gently and slowly advance the PBLADE. **Always visually observe the blade as it is inserted to prevent damage to the patient's lips, teeth, and other soft tissues during insertion. Do not put pressure on the teeth, and make sure that the tongue is not pushed inward while inserting the PBLADE.** Reposition the device to the midline of the mouth once inserted.

Observe the monitor to visualize the airway and epiglottis. Suction any secretions with a 12 French suction catheter inserted through the suction catheter insertion port. Perform suctioning while observing the location of the suction catheter tip on the monitor. Visualize the epiglottis. Slide the epiglottis lifting blade underneath the epiglottis. Gently elevate the device to elevate the epiglottis. Gently manipulate the device until the glottis is aligned with the target symbol on the monitor screen. Gently advance the ET tube through the glottis until the ET tube marker line reaches the glottis. Inflate the ET tube cuff. Detach the ET tube from the hooks. Gently remove the PBLADE from the patient's mouth while securely holding the ET tube in place. Confirm proper ET tube position.

ALTERNATIVE TECHNIQUES

The Emergency Physician cannot be positioned above the patient's head in rare circumstances. In these cases, an inferior or lateral approach can be used. Insert the PBLADE as described above. Connect the AWS to a video monitor, or if using the S100L, adjust the position of the screen using the hinge to obtain an optimal viewing angle. Visualize the epiglottis. The remainder of the technique is exactly as described previously. It may feel awkward to manipulate the device and ET tube from a position inferior or adjacent to the patient's head.

Insertion of the fully assembled AWS may not be possible in obese patients and others with large chests.¹⁶ Separate the PBLADE loaded with the ET tube from the AWS. Insert the PBLADE into the oropharynx under direct visualization. Gently and carefully reattach the AWS to the PBLADE. **Be careful not to traumatize the patient's lips, teeth, or airway soft tissues.** Reassemble the device and proceed with intubation as described above.

This technique can be used for patients in which deep sedation and induction are contraindicated. An off-label technique for awake intubation has been described.¹⁷ Assemble the device. Attach a Bodai connector to the proximal end of the ET tube. Insert a 14 French suction catheter into the lumen of the ET tube via the Bodai connector. Attach the breathing circuit to the other branch of the Y-connector to administer oxygen at a rate of 10 L/min. Insert a tracheal spray tube, smaller than 12 French, through the original suction channel. Attach a syringe loaded with topical anesthetic solution to the proximal end of the tracheal spray tube. Suctioning can be performed through the ET tube as the PBLADE is advanced. The topical anesthetic agent can be delivered via the spray tube. Visualize the glottis. Administer the local anesthetic solution to and through the vocal cords prior to advancing the ET tube through the glottic opening.

COMPLICATIONS

Placement of the AWS may not be possible in patients with limited mouth opening when using the standard PBLADE, which is 25 mm wide.¹⁰ Use the thin PBLADE, which is 9 mm, or a surgical airway. Visualization of the vocal cords can be limited by secretions.¹⁸ **Have a suction catheter always available.** Insert the PBLADE slowly to prevent it from being inserted into pooled secretions. Visualization may not be possible despite aggressive suctioning with particulate matter or severe bleeding in the airway. **Be prepared to use an alternative**

airway device if this occurs. Incorrect or forceful insertion can result in dental trauma and soft tissue injuries. The other complications associated with this device are the same as those of DL (Chapter 18).

The ET tube maneuverability is limited when loaded onto the PBLADE. Use a bougie in cases where visualization of the glottis is possible but intubation is not successful. Align the PBLADE and ET tube as much as possible with the glottis. Pass a bougie through the ET tube. Advance and direct the bougie through the vocal cords. Slowly and gently advance the ET tube over the bougie under video guidance.¹⁸

VL offers a quicker time to visualization and insertion of the ET tube. The time from initiation of intubation to ventilation is not significantly different from traditional DL.¹⁵ It is speculated that this is due to the increased time it takes to remove the ET tube from the AWS after intubation. The time to ventilation can be reduced by beginning manual ventilation before removal of the PBLADE from the oropharynx. Consider this technique in patients who are hypoxic after intubation.¹⁰

MCGRATH LARYNGOSCOPE

The McGrath Laryngoscope (Physio-Control Inc., Redmond, WA) is a VL that is designed to provide a clear video view of the glottis with minimal change in the traditional DL technique. It is a portable VL and modeled after the traditional Macintosh laryngoscope blade (**Figure 20-2A**). It is a refinement of the "smart scope" laryngoscope developed by Matt McGrath. He won the 1999 Royal Society of Arts student design competition as a British university student for outstanding design achievement for his portable laryngoscope with a small video monitor attached to the handle.¹⁵

INDICATIONS AND CONTRAINDICATIONS

The McGrath laryngoscope is indicated for elective and emergent intubations. It is useful in difficult intubations in which the three airway axes may be difficult to align (e.g., cervical spine immobilization, high Cormack and Lehane grade airways, limited mouth openings, and tongue edema).^{2,19-21} It is indicated for use in pediatric patients weighing 15 kg or more.²² The McGrath laryngoscope is not indicated for use in awake intubations.²³ The McGrath provides clearer glottic views, greater ease of intubation, and less complications than DL with a Macintosh blade when used by inexperienced providers.²³ There are no contraindications using the VL.

EQUIPMENT

The Series 5 McGrath consists of the handle module, the camera stick, and the blade (**Figure 20-2A**). The handle module houses the power source and the video monitor. The nonslip rubberized handle contains a single AA battery and the power switch. At the crown of the handle module rests the 1.7 inch color LCD monitor. The monitor can rotate around the handle 360° and can be tilted to adjust the viewing angle. The camera stick houses the camera and light source. Its length is adjustable to produce a blade length ranging from a Macintosh size 3 to 5 blade. The disposable single-use plastic blade fits over the distal camera stick to protect the camera and to assist in lifting of the epiglottis. The McGrath MAC is a newer version without the adjustable length. The McGrath EMS is similar but built tough for field use and orange colored.

PREPARATION

Preparing the Series 5 McGrath for use is quite simple. Unscrew the cap on the top of the handle and insert the AA battery. The top of the handle is opened by turning it counterclockwise and closed by turning it clockwise. Apply the camera stick onto the handle. Pull

A

B

FIGURE 20-2. The McGrath Laryngoscope. **A.** The Series 5 (left) and the MAC (right). **B.** The blade has been inserted and the ET tube is advanced through the vocal cords. (Photos courtesy of Physio-Control Inc., Redmond, WA.)

out the release safety catch at the base of the handle and rotate it so that it is aligned parallel to the long axis of the camera stick. Slide the camera stick into the base of the handle. Return the safety catch to its original position. Firmly attach the disposable sterile laryngoscope blade to the camera stick. Slide it over the camera stick until it firmly latches. Adjust the blade length by sliding the camera stick through the clamp handle. A click will be heard for each adjustment in blade size. Turn the power on by pressing the power switch on the top of the handle. The LED light on the LCD monitor will be continuously lit if there is adequate battery power. The battery power is low if it blinks and the battery should be changed prior to using the device. The McGrath MAC and EMS models have a fixed length and are not adjustable like the Series 5.

TECHNIQUE

The intubation technique using any version of the McGrath is similar to DL.²³ Insert the tip of the blade in the midline and superior to the tongue (**Figure 20-2B**). Slowly advance the blade and rotate its tip toward the larynx in the sagittal plane until the epiglottis is visualized via direct visualization or via indirect visualization using the camera monitor. Advance the blade further until its tip rests in the vallecula. Gently lift the McGrath until the glottis is visualized. Gently elevate the device to elevate the epiglottis. The monitor should show the vocal cords and surrounding structures (**Figure 20-2B**). Slightly withdraw the blade until the desired view is obtained if only a portion of the vocal cords are visible. Gently manipulate the device until the glottis is centered on the monitor screen. Insert and advance the proper size ET tube through the vocal cords with the assistance of either a malleable stylet or a bougie. Make the ET tube with a stylet hockey stick shaped 5 cm from the tip to optimize maneuverability.¹⁹ Gently advance the ET tube through the glottis until the ET tube marker line reaches the glottis. Inflate the ET tube cuff. Withdraw the stylet or bougie. Gently remove the blade from the patient's mouth while securely holding the ET tube in place. Confirm proper ET tube position.

ALTERNATIVE TECHNIQUES

An alternative technique can be performed in those with limited mouth opening or chest anatomy that prevents placement of the device into the oropharynx using the traditional DL technique.²⁰

Disarticulate the Series 5 camera stick from the handle to facilitate placement of the blade into the oropharynx. Insert the camera stick and blade similar to introducing a tongue depressor into the oral cavity. Attach the handle to the camera stick. Intubate the patient as previously described.

COMPLICATIONS

Apply greater upward force to lift the epiglottis if the epiglottis obstructs visualization of the glottic opening. The plastic blade may be used in the same manner as a Miller blade. Redirect the blade to lift the epiglottis, visualize the glottis, and intubate as previously described. Incorrect or forceful insertion can result in dental trauma and soft tissue injuries. The other complications associated with this device are similar to those of DL (Chapter 18).

Check for fogging if the monitor image is unclear. Apply an anti-fog solution as needed.¹⁵ A blurred image can result from the blade not being latched onto the camera stick. Ensure the video lens is flush with the viewing window of the blade. Remove the blade from the device and clean the camera lens with a gentle soft wipe if neither of these maneuvers is successful.

A grade I view may be obtained of the glottis yet the ET tube cannot be advanced into the trachea. This may be due to the acute bend and long flange of the blade.²⁴ The device provides a view of the glottis without the alignment of the three airway axes. This requires the ET tube to have a more acute bend than normally used for DL. Place an acute bend in the styletied ET tube approximately 7 to 10 cm from the tip. Another option is to advance the ET tube into the glottis while simultaneously withdrawing the stylet and not inserting the styletied ET tube into the glottis.

BERCI-KAPLAN DCI VIDEO LARYNGOSCOPE

The Berci-Kaplan DCI VL is a video Macintosh intubating laryngoscope developed by Drs. Kaplan, Ward, and Berci (Karl Storz Endoscopy-America, El Segundo, CA).²⁵ It incorporates micro video imaging technology into a traditional laryngoscope blade. This reduces the learning curve in operating this device for those experienced with traditional DL. It is ideal for use when training

FIGURE 20-3. The Berci-Kaplan DCI Video Laryngoscope. (Photo courtesy of Karl Storz Endoscopy-America, El Segundo, CA.)

the novice in the traditional DL technique.^{25,26} A fiberoptic bundle extends from the proximal end of the laryngoscope blade allowing for a larger angle of viewing and a magnified view of the airway. This VL has been marketed for used as part of an “all-in-one” video intubation system (**Figure 20-3**).

INDICATIONS AND CONTRAINDICATIONS

The VL is indicated for normal and difficult intubations in pediatric and adult patients. The large video screen makes this device particularly useful for difficult intubations requiring external manipulation of the airway by an assistant. There are no contraindications to using the VL.

EQUIPMENT

The VL device consists of various laryngoscope blades, the DCI camera head, and the control unit (**Figure 20-3**). The VL blade houses the camera optics. It is available in Macintosh sizes (3 and 4), Miller sizes (0, 1, and 3), and the Doerges universal blade style. The lens provides a viewing angle of 60° to 80° depending on the type of blade. The laryngoscope blade is integrated into the ergonomic handle (**Figure 20-3**). The handle attaches to the camera head, the interface between the control unit and the VL. Other interchangeable airway devices can be attached to the control unit including the Bonfil’s scope, Brambrinck scope, and fiberoptic scope (**Figure 20-3**). The control unit incorporates the light source, image processing module, imaging memory, power supply, keyboard, and color LCD monitor.

PREPARATION

Attach the selected laryngoscope blade to the camera head. Turn on the control unit. The laryngoscope blades can be changed with the control unit powered on. Apply medical-grade antifogging solution onto the camera lens.

TECHNIQUE

An advantage of this VL is that the intubation technique does not differ from that of traditional DL. **The added benefit of indirect visualization is that less force is needed to visualize the glottis.** An assistant can view the monitor to facilitate external manipulation of the larynx to bring the glottis into view. The ET tube can be passed through the glottic opening under direct or video-assisted visualization. Gently advance the ET tube through the glottis until the ET tube marker line reaches the glottis. Inflate the ET tube cuff. Withdraw the stylet or bougie. Gently remove the blade from the patient’s mouth while securely holding the ET tube in place. Confirm proper ET tube position.

ALTERNATIVE TECHNIQUES

A limitation of this VL is its relatively large handle with cables protruding from its proximal end. This can impede intubation in patients with cervical spine immobilization, large chests, or short necks.²⁶ Insert and advance the laryngoscope blade into the patient’s mouth from the side. Gently rotate and return the laryngoscope handle into the midline once the blade is deep enough and the handle can clear the chest. **Be careful not to push the tongue posteriorly.** Proceed with intubation as previously described.

COMPLICATIONS

A known issue with this VL is lens fogging. This is particularly problematic in patients who are not fully paralyzed. Prevent this by applying a medical-grade antifogging solution, a thin layer of water-soluble lubricant, or the patient’s saliva on the lens.²⁶ Blood and other secretions can obscure the view. Reduce this by not inserting the laryngoscope blade into pooled secretions and by using suctioning.²⁶ Incorrect or forceful insertion can result in dental trauma and soft tissue injuries. The other complications associated with this device are similar to those of DL (Chapter 18).

Common barriers to purchasing this device are its cost and its large size. The large size of the control unit limits its portability unless it is placed on a rolling cart. The control unit can be used in conjunction with several other Storz airway devices. This makes it a worthwhile investment in Emergency Departments that use other compatible airway devices.²⁶

C-MAC VIDEO LARYNGOSCOPE

The C-Mac (Karl Storz Endoscopy-America, El Segundo, CA) is a VL system released in 2009 (**Figure 20-4A**). It replaces the original VL by Karl Storz. It has numerous advantages including being more compact and portable, a decreased blade width, and improved video technology. The original VL incorporated a fiberoptic camera and video system into a traditional laryngoscope blade. The C-Mac abandons this technology for a CMOS micro video camera. This allows the video system to be incorporated within the laryngoscope blade. The CMOS micro video camera provides an enhanced area of view and does not have the issue of fogging.

INDICATIONS AND CONTRAINDICATIONS

The C-Mac VL is indicated for normal and difficult intubations in pediatric and adult patients. There are no contraindications using the VL.

EQUIPMENT

The handheld portable C-Mac consists of the blade, the electronic module, and the monitor (**Figure 20-4B**). The blade reproduces the curvature of the traditional Macintosh blade and is composed of

A

B

C

D

FIGURE 20-4. The C-Mac Video Laryngoscope. **A.** The C-Mac system. **B.** The blades available for the C-Mac system. **C.** The C-Mac. **D.** The C-Mac PM. (Photos courtesy of Karl Storz Endoscopy-America, El Segundo, CA.)

stainless steel. The proximal end has been flattened to reduce the amount of mouth opening required for intubation and to reduce the risk of oral trauma. The lens is located approximately one-third of the distance from the tip of the blade and provides a 60° field of vision. The CMOS chip housed in the blade provides lens antifogging and an optimal image quality. The blade is available in several Macintosh sizes (2, 3, and 4) and Miller sizes (0 and 1), and there is a hyperangulated adult and pediatric D-Blade that is similar to traditional Glidescope blades.

The electronic module is the interface between the laryngoscope blade and the monitor unit. The module permits easy operator-controlled video documentation. Images can be recorded as still shots or video sequences using the incorporated key pads.

The 7 inch, high-resolution monitor is housed in an impact-resistant and splash-protected plastic body. The top of the monitor has an integrated secure digital (SD) memory card and USB port

for video recording and transfer. The monitor automatically white balances when it is turned on. The monitor image can be further modified using the touch key controls to the right of the monitor screen. The monitor device houses a lithium ion battery with a 2 hour operating time when fully charged.

Several new attachments make the C-Mac quite versatile (**Figure 20-4A**). The C-Mac PM incorporates a 2.4 inch LCD monitor that inserts into the laryngoscope handle (**Figure 20-4C**). This eliminates the electronic module, cord, and base unit. The LCD monitor unit can be used with all the C-Mac laryngoscope blades. The C-Mac S is a single-use version of the original C-Mac that can tolerate temperatures up to 65°C for sterilization. The C-Cam is a camera head that attaches to the monitor unit. Through this, numerous other airway devices can be attached including all Storz airway devices, the Bonfil's scope, and other fiberoptic scopes (**Figure 20-4A**).

PREPARATION

Preparing the C-Mac for use is quite simple.²⁷ Insert the electronic module into the VL blade receptacle. The blade can later be changed while the monitor is on. Insert the yellow connection cord of the electronic module into the yellow socket on the back of the monitor. Connect the power cord into the blue socket on the back of the monitor and plug in the power supply if the battery symbol turns red. The battery sign will indicate that the unit is charging. Insert an SD card into the monitor for recording and image capture. An alternative is to connect an external video recording source into the USB port.

Turn on the C-Mac using the power switch located at the left lower corner of the display monitor. Check the camera for proper functioning by focusing the lens under the laryngoscope blade on a hand. The camera's light source will be visible on the hand. The light intensity, color saturation, and contrast can all be adjusted using the key pads located on the monitor. Wipe the lens with a soft cloth or lens tissue if the video image is blurry. Clean the contacts of the electronic module if wiping the lens does not improve the image. Recording can be performed by pressing the record button located on the laryngoscope blade handle.

TECHNIQUE

The intubation using the C-Mac is exactly the same as using traditional DL (Chapter 18).²⁷ Insert the laryngoscope blade into the right side of the oral cavity under direct visualization. Move the VL to the midline and catch the tongue on the flange of the blade. Advance the blade past the oropharynx and into the vallecula. **Be careful to not push the tongue posteriorly.** Lift the laryngoscope handle upward to improve visibility. Visualization can be performed by direct visualization or via the monitor. Gently advance the ET tube through the glottis until the ET tube marker line reaches the glottis. Inflate the ET tube cuff. Withdraw the stylet or bougie. Gently remove the blade from the patient's mouth while securely holding the ET tube in place. Confirm proper ET tube position.

The C-Mac PM is similar to the McGrath. Turn on the device. Insert it into the midline of the patient's mouth and advance it into the vallecula. Adjust the monitor if needed. Insert, verify the location, and secure the ET tube.

COMPLICATIONS

Incorrect or forceful insertion can result in dental trauma and soft tissue injuries. The other complications associated with this device are similar to those of DL (Chapter 18).

GLIDESCOPE

The Glidescope (Verathon Inc., Seattle, WA) combines a video camera with a patented antifog system into a portable laryngoscope blade and monitor system. The blade design modifies the traditional Macintosh blade curvature to provide a more anterior view of the larynx. The Glidescope was developed by a Canadian surgeon.¹³ Modifications in the basic design have resulted in several models (**Figure 20-5**). The Glidescope AVL uses a single-use disposable blade for a rapid turnaround without sterilization between uses.²⁸ The Ranger Glidescope models provide a compact, high-impact device originally intended for military and prehospital use.²⁹ The Glidescope Titanium provides two different blade style options, the original low-profile angulated design that the previous Glidescope models are known for and a Macintosh-style blade that can allow VL and DL.²⁹

INDICATIONS AND CONTRAINDICATIONS

The Glidescope is indicated for routine and difficult intubations. It is particularly useful for patients requiring cervical spine immobilization. It has been demonstrated to have a significant advantage over the Macintosh blade in the patient with tongue edema.³⁰ It can be used in pediatric patients who weigh as little as 1.8 kg. There are no reported contraindications to using this device.

EQUIPMENT

There are three current Glidescope models (i.e., Titanium Glidescope, Glidescope AVL, and Ranger Glidescope). Some Emergency Departments may use an older version known as the Glidescope GVL. The primary components of the Glidescope are the blade and the video monitor. All the blade models incorporate an auto-focusing CMOS camera, LED light source, and patented antifogging mechanism housed inside of a medical-grade plastic shell. The original Glidescope blade begins with the traditional Macintosh blade and adds a 60° curvature at the midpoint. This allows for a more anterior view of the airway with less lifting force required.¹⁵ The camera lens lies at the distal aspect of the blade's curve to protect it from secretions while providing a close-up view of the glottis. The Glidescope produces better glottic visualization than traditional DL.³¹⁻³⁴

The traditional Glidescope blade is a reusable integrated blade and handle. It is available in four sizes. The traditional Ranger blade consist of a reusable integrated blade, handle, and video cable that cradles into the body of the Glidescope monitor. It is currently available in two sizes. The Ranger single-use blades are available in six sizes (i.e., 0, 1, 2, 2.5, 3, and 4). These are available in both LoPro and MAC blade styles.

The Glidescope AVL and Ranger single-use blade consists of a video baton and a STAT blade. The video baton houses the CMOS camera, LED light, and antifogging mechanism. The baton is inserted into a one-time use STAT blade constructed of medical-grade plastic. The STAT blade is shaped like the traditional Glidescope blade and provides the protective cover for the baton, reducing the risk of transmitting an infection.³⁰ This dramatically reduces turnaround by eliminating the 30 minutes required to clean traditional blades prior to reuse.^{28,30} The baton is available in two sizes and four blade sizes.

The blades are connected to the video monitor with a video cable. The traditional Glidescope, the Cobalt Glidescope, and the Titanium Glidescope have a 7 inch, nonglare, color LCD monitor. Housed within the monitor is the battery and power device. The monitor includes the power switch and control pads that allow adjustment of the video image. The Ranger versions have a rugged shell for field use and a 3.5 inch color, nonglare LCD. The body of the monitor incorporates a cradle for the blade. The Ranger Glidescope uses a rechargeable lithium ion battery. The Ranger can be used for 90 continuous minutes or approximately 20 intubations.²⁹ The Titanium Glidescope video monitor has video output and recording capabilities to allow it to be connected to a larger monitor or have videos of intubations saved (e.g., for educational or quality-improvement purposes).

Many of the Glidescope models come with the GlideRite rigid stylet, although it is not required for intubation (**Figure 20-5**). It is a rigid stylet designed to complement the angle of the Glidescope blades. Initial studies indicate that intubation with the GlideRite rigid stylet offers no advantages over the standard malleable stylet.³⁵ More recent literature demonstrates an increased success rate in first-pass and successful intubation in the Emergency Department with the Glidescope when the rigid stylet is used instead of a malleable stylet.³⁶

B

C

D

E

FIGURE 20-5. The Glidescope Video Laryngoscope. **A.** The Glidescope GVL system. **B.** The Glidescope AVL system. **C.** The Glidescope Ranger system. **D.** The Glidescope Titanium. **E.** Single-use titanium blades. (Photos courtesy of Verathon Inc., Seattle, WA.)

PREPARATION

Preparing the Glidescope for use is quite simple for all models. Attach the Glidescope blade to the monitor using the video cable. Turn on the device, and it is ready for use. For the Cobalt and single-use Ranger models, insert the baton into the STAT blade. A click will be heard to confirm that the blade has been securely attached. It is not required to use the GlideRite rigid stylet. It is recommended when using a traditional malleable stylet to curve it to model the shape of the Glidescope blade to facilitate manipulation of the ET tube.^{15,28,29,37-39}

TECHNIQUE

The intubation technique using the Glidescope is similar to that of traditional DL (Chapter 18).^{28,29} Insert the blade into the midline of the oral cavity. Advance the blade under direct visualization until its tip reaches the pharynx. **Be careful to not push the tongue posteriorly.** Continue to advance the blade while observing the monitor to identify the epiglottis. Advance the blade into the vallecula. Lift the blade, if necessary, to elevate the epiglottis. Insert the ET tube under direct visualization until its tip nears the tip of the laryngoscope blade. Guide the ET tube toward the glottic opening. Pull the GlideRite stylet back approximately 2 cm and advance the ET tube through the vocal cords. This will facilitate passage of the ET tube through the vocal cords while reducing the potential for injury. Continue to gently advance the ET tube through the vocal cords until the ET tube marker line reaches the glottis. Inflate the ET tube cuff. Withdraw the stylet. Gently remove the blade from the patient's mouth while securely holding the ET tube in place. Confirm proper ET tube position. The option of intubating with direct visualization and confirming via video is available when using the Titanium Glidescope.

There are several troubleshooting tips when problems arise using the Glidescope. Positioning the blade to the left of midline makes room for the ET tube in small or limited-opening mouths. The view may be improved by backing up the blade a little. Trouble advancing the ET tube is eliminated with the thumb advancing it. A limited or restricted view (i.e., not a Cormack-Lehane grade 1) may aid in advancing the ET tube into the airway.⁴⁰⁻⁴²

COMPLICATIONS

Use of a Glidescope for intubation can increase the time to advance the ET tube through the vocal cords when compared to intubation using DL.¹² This difference in time decreases with increased use and familiarity with the device.⁴³ It is strongly recommended that novice operators use the Glidescope on mannequin models and for "routine" intubations prior to using it as a rescue device for difficult intubations.

Intubation with the Glidescope can be difficult in patients with small mouths or large tongues due to the limited area for the blade and ET tube. It may be difficult to pass the ET tube into the larynx. **Do not blindly insert the ET tube as it may cause injury to the oropharyngeal tissues.**⁴⁴ Insert the Glidescope under direct visualization and then move it to the left if space is a problem. The ET tube can then be inserted under direct visualization. The view on the monitor of the larynx may appear deviated.⁴⁴ Manipulate the Glidescope to obtain an optimal view on the monitor. An additional technique is to shape the ET tube into a hockey stick or J-curve to facilitate advancement and manipulation from the lateral aspect of the mouth.¹² Incorrect or forceful insertion can result in dental trauma and soft tissue injuries.^{45,46} The other complications associated with this device are similar to those of DL (Chapter 18).

FIGURE 20-6. The Clarus Video System. **A.** The system. **B.** The disposable tube stop and oxygen port. (Photos courtesy of Clarus Medical LLC, Minneapolis, MN.)

CLARUS VIDEO SYSTEM

The Clarus video system (Clarus Medical LLC, Minneapolis, MN) is a device that can be modified with various accessories for use as a VL, ET tube exchange catheter, flexible scope, and malleable stylet.⁴⁷⁻⁵⁰ It incorporates the video, lighting, power, and monitor system into one handheld product (**Figure 20-6**). The malleable video stylet shaft and the disposable VL blade are designed for intubation.⁴⁷ The optional flexible scope is detachable for use as an ET tube exchange catheter.

INDICATIONS AND CONTRAINDICATIONS

The Clarus Video System is intended for use in performing and confirming placement of an ET tube. It is indicated for use alone or as a video stylet in conjunction with a DL. It can be used for routine and difficult intubations. There are no contraindications to using this device.

EQUIPMENT

The handle of the video system houses the rechargeable power unit. The color LCD display monitor attaches to the handle. The monitor viewing angle can be adjusted with an easy to reach thumb control. The light intensity can be adjusted using controls on the handle. The handle contains the external video connector and the battery charger port. The distal lens, light LED, and camera are housed in the distal tip of the video stylet shaft.

A disposable tube stop fits on the malleable video stylet to hold the ET tube at the desired height on the stylet (**Figure 20-6B**). An oxygen port can be connected to the tube stop to supply supplemental oxygen through the ET tube. A detachable and flexible video scope is available for use during ET tube exchange.

PREPARATION

Preparing the Clarus video scope for use requires the device to be assembled. Place the disposable tube stop over the stylet shaft. Attach the oxygen port to the matching circular receptacle on the tube stop. Attach oxygen tubing to this port if desired. The oxygen flow rate and pressure must be monitored to prevent barotrauma.⁴⁷

Apply an ET tube with a minimum diameter of 5.5 mm and a maximum length of 34.3 cm over the distal tip of the stylet and fitted to the tube stop. Consider applying water-soluble lubricant onto the stylet to facilitate this process.⁴⁷ Consider applying a medical-grade antifogging agent to the lens on the stylet tip. Adjust the tube stop so that the stylet tip rests just proximal to the distal end of the ET tube to provide optimal visualization and reduce the potential for tissue trauma. Tighten the clamp screw on the tube stop to fix the position of the ET tube onto the stylet shaft. The image on the monitor screen will automatically focus when the device is turned on. The illumination can be adjusted using the dial on the monitor.

TECHNIQUE

The device can be used for intubation with a traditional DL. Insert the laryngoscope and attempt to visualize the vocal cords and other surrounding structures. Insert the ET tube on the Clarus stylet if the vocal cords are visualized similar to performing traditional DL (Chapter 18). Visualization of the airway structures may not be possible in patients with difficult airways or those requiring cervical spine immobilization. Use the monitor on the Clarus Scope to direct, manipulate, and advance the styletted ET tube through the glottis. Gently advance the ET tube through the glottis until the ET tube marker line reaches the glottis. Inflate the ET tube cuff. Withdraw the Clarus stylet. Gently remove the laryngoscope blade from the patient's mouth while securely holding the ET tube in place. Confirm proper ET tube position.

COMPLICATIONS

Incorrect or forceful insertion can result in dental trauma and soft tissue injuries. The other complications associated with this device are similar to those of DL (Chapter 18).

KING VISION VIDEO LARYNGOSCOPE

The King Vision Video Laryngoscope (Ambu USA, Columbia, MD) and the King Vision aBlade Video Laryngoscope are battery operated, rigid, and portable digital VLs (**Figure 20-7**). They are simple to use and understand. The King Vision is significantly less expensive than most other VLs. The device uses organic light emitting diode (OLED) technology.

INDICATIONS AND CONTRAINDICATIONS

The King Vision is indicated for routine and difficult intubations in adolescents and adults. The laryngoscope blade is equivalent to a Macintosh #3 size blade. There are no contraindications to using this device if a Macintosh #3 blade is appropriate for intubation. The King Vision aBlade can be used for any type of airway, whether routine or complicated. It is small and lightweight enough to be kept in an airway cart as a primary intubation tool or as a backup.

FIGURE 20-7. The King Vision Video Laryngoscope. (Photo courtesy of Ambu USA, Columbia, MD.)

EQUIPMENT

The King Vision consists of the color OLED monitor base unit that attaches to a disposable laryngoscope blade (**Figure 20-7**). The two pieces snap together. The monitor unit houses three AAA batteries as the power source, the on/off switch, and a mini USB port for video output to a display monitor or recording device. The batteries provide at least 90 minutes of "on time." The OLED monitor offers increased contrast at a lower cost than LCDs and LEDs. The monitor is brighter, faster, lighter, thinner, and uses less power than LCDs.

The blades are plastic, single-use, and disposable, and are available in two styles (i.e., with and without an ET tube channel). The channeled blade accommodates a 6.0 through 8.0 ET tube. The blade is only available in a Macintosh #3 size. It differs from the standard Macintosh #3 blade in that it is slightly shorter and wider. The blade is smaller than most VLs. It requires a minimum mouth opening of 13 mm for the standard blade and 18 mm for the channeled blade. A CMOS camera and LED light source are mounted on the disposable blade. The lens has an antifog coating.

PREPARATION

Preparation of the King Vision is quick and simple. Ensure that the power is off. **Applying a blade with the unit powered on will result in image distortion.** Choose a laryngoscope blade with or without a channel. Slide the blade onto the monitor piece and snap it in place. The front and back of the blades and the monitor unit are color coded to facilitate proper orientation. The blade with a channel can be used with or without an ET tube inserted into the channel. Load an appropriate-sized ET tube, if desired, without a stylet into the well-lubricated channeled blade. Use only water-soluble lubricant. Avoid placing lubricant over the lens. Align the distal tip of the ET tube at the end of the channel. Turn on the device. Replace the batteries if the battery indicator light is flashing red. Observe the monitor to ensure that an image is present and clear. The image will be distorted if the unit was powered on when the blade was attached. Simply turn the unit off and then back on to obtain a clear image. The tip of the ET tube, if using the channeled blade, should not be visible on the monitor. If it is visible, pull the ET tube back until the tip is aligned with the tip of the laryngoscope blade and no longer visible in the monitor.

TECHNIQUE

The technique for intubation is similar to traditional DL if using the standard blade or the channeled blade without loading an ET tube (Chapter 18). Insert the blade in the midline and advance it into the oropharynx. **Be careful to not push the tongue posteriorly.** Continue to advance the blade toward the vallecula while observing the monitor. The blade can be placed into the vallecula like a Macintosh blade or can be used to elevate the epiglottis like a Miller blade. View the monitor while directing, manipulating, and advancing the styletted ET tube through the glottis. Gently advance the ET tube through the glottis until the ET tube marker line reaches the vocal cords. Inflate the ET tube cuff. Withdraw the device. Gently remove the laryngoscope blade from the patient's mouth while securely holding the ET tube in place. Confirm proper ET tube position.

A slight technique modification is required if mounting an ET tube into the channeled blade. Insert the blade as described previously. Center the glottic opening on the screen. Slide and advance the ET tube along the channel and through the vocal cords. Minor manipulation of the blade may be required to align and advance the tip of the ET tube through the vocal cords. A bougie can be loaded through the ET tube to facilitate intubation.

COMPLICATIONS

Imaging can be compromised by excessive secretions or blood in the oropharynx. Incorrect or forceful insertion can result in dental trauma and soft tissue injuries. The other complications associated with this device are similar to those of DL (Chapter 18).

ALTERNATIVE DEVICES

The above devices are representative devices used in the Emergency Department. Other devices are listed briefly below and used like the devices already described.

COPILOT VL

The Copilot VL (Magaw Medical, Fort Worth, TX) is small and portable (**Figure 20-8**). It consists of the display monitor, handle video blade, and disposable sheaths.⁵¹ A cable attaches the handle to the monitor. It is lower in cost than other VLs. The side channel can be used to guide a bougie toward the screen image. The lithium battery is rechargeable and can be used for 2 hours continuously before the charge runs out. The monitor has a battery status indicator. The

A

FIGURE 20-8. The Copilot Video Laryngoscope. (Photos courtesy of Magaw Medical, Fort Worth, TX.)

FIGURE 20-9. The Intubrite Video Laryngoscope. (Photo courtesy of Intubrite LLC, Vista, CA.)

Copilot VL has an antifog mechanism that requires the device to be on for 30 seconds prior to laryngoscopy. The proprietary rigid stylet can be used in the ET tube instead of a standard stylet. The Copilot VL is only available in adult sizes 3 and 4. The contaminated disposable sheath can be removed from the device hands-free. The Copilot VL is appropriate for prehospital, Emergency Department, and in-hospital use.

INTUBRITE VL

The Intubrite VL (Intubrite LLC, Vista, CA) has a 3.5 inch monitor attached to the laryngoscope (**Figure 20-9**).⁵² It records images and video to the removable SD card. It is available in two models (i.e., VLS 8800 and VLS Edge), is durable, and is made of stainless steel. The Intubrite VL contains a high-resolution camera, data output port, and a video output port. The VLS Edge uses reusable blades or sheaths in six sizes. The VLS 8800 blades come in sizes 2, 3, and 4A for anterior airways.

B

FIGURE 20-10. The VividTrac Video Laryngoscope. (Photo courtesy of Vivid Medical Inc., Palo Alto, CA.)

VIVIDTRAC VL

The VividTrac (Vivid Medical Inc., Palo Alto, CA) is available in an adult and pediatric version (**Figure 20-10**).⁵³ The adult version uses ET tube sizes 6.0 to 8.5, and the pediatric version uses ET tube sizes 4.0 to 6.0. The shape is anatomically designed. The VividTrac contains a stainless steel blade, ET tube channel, and a rounded tip. It contains an antifog mechanism. The 3 foot USB cord is integrated and attaches to a computer or monitor. The device is single-use, contains and needs no battery, is maintenance-free, and requires no cleaning.

VENNER APA VL

The Venner APA VL (Venner Medical Intl., Saint Helier, Jersey) is a battery-powered device with a CMOS camera (**Figure 20-11**).⁵⁴ A 3.5 inch high-resolution monitor is mounted on an ergonomic handle. The light source is mounted on the distal tip and increases the intensity. Four blades are available (i.e., Mac 3, Mac 4, difficult airway blade [DAB], and an unchanneled difficult airway blade [U-DAB]). A video port connects the device to an external monitor.

FIGURE 20-11. The Venner APA Video Laryngoscope. (Photo courtesy of Venner Medical Intl., Saint Helier, Jersey.)

FIGURE 20-12. The TruView PCD Video Laryngoscope. (Photo courtesy of Truphatek Intl. Ltd., Netanya, Israel.)

TRUVIEW PCD VL

The TruView PCD VL (Truphatek Intl. Ltd., Netanya, Israel) is available in an “R” model and a pediatric model (**Figure 20-12**).⁵⁵ The “R” model uses blades in sizes 0, 1, 2, 3, and 4. The pediatric model uses blades in sizes 0, 1, 2, and 3. It can be used in adults with restricted mouth opening. The blades have a built-in jet oxygen cleaning system. The devices have soft-feel rechargeable power handles with LED illumination. The devices have a 5.5 inch monitor and allow for recording videos and photos.

UE SCOPE

The UE Scope (UE Medical Devices, Newton, MA) can be used in neonates through adults (**Figure 20-13**).⁵⁶ It contains a rechargeable battery for over 90 minutes of operation, an adjustable grip, an adjustable 2.5 inch monitor, and an antifog mechanism. The angulated blades are meant for anterior airways and are available in five reusable sizes (i.e., 0, 1, 2, 3, and 4) and three disposable sizes (i.e., 2, 3, and 4). The camera points upward to provide a 60° field of view. A proprietary rigid stylet can be used.

AIRTRAQ VL

The AirTraq VL (Prodol Meditec SA, Las Arenas, Spain) is available in an all-in-one design (**Figure 20-14**).⁵⁷⁻⁶² The Avant model has disposable blades/sheaths, a flip screen that rotates, and is compatible with magnetic resonance imaging (MRI). The SP model is completely disposable and MRI compatible. Both models are equipped with a Wi-Fi camera that allows viewing on the device, an attachable

FIGURE 20-13. The UE Scope. (Photo courtesy of UE Medical Devices, Newton, MA.)

A

B

C

FIGURE 20-14. The Airtraq Video Laryngoscope. **A.** Avant model. **B.** SP model. **C.** Wi-Fi camera. (Photos courtesy of Prodol Meditec SA, Las Arenas, Spain.)

camera, or an attachable monitor. A channel guide does not require a stylet and allows for a bougie. They can be used on infants through adults (i.e., ET tube sizes 2.5 to 8.5). Adults with restricted mouth opening can use the pediatric version with the adult-sized ET tube. It can be used on morbidly obese patients. The Airtraq causes less blood pressure and heart rate alterations than DL.

TOTALTRACK VLM

The TotalTrack VLM (Medcom Flow SA, Barcelona, Spain) is the only available VL mask (**Figure 20-15**).⁶³⁻⁶⁷ It allows intubation and ventilation while directly visualizing the airway. It is available in two adult versions. One uses ET tubes sized 7.5 to 8.5, and the other uses size 6.0 to 7.5 ET tubes. There are two aspiration ports (i.e., gastric and laryngeal). The device contains a 2.5 inch monitor screen and an SD memory card slot and is battery operated. The output

jack allows attachment to a monitor. The TotalTrack can be inserted from any intubator position.

CLEARVUE VL

The ClearVue VL (Infinium Medical, Largo, FL) comes with a 3.5 inch display monitor, rechargeable lithium ion battery, and an anti-shatter screen (**Figure 20-16**).⁶⁸ It is available with disposable and reusable blades. The ClearVue VL has antifog technology, a quick-shot camera button, and a 66° field of view.

SUMMARY

There is a growing array of video intubation devices available with varied designs. This includes those that embed the camera into the laryngoscope blade, those that embed the video camera into a scope

FIGURE 20-15. The TotalTrack VLM. (Photos courtesy of Medcom Flow SA, Barcelona, Spain.)

or stylet for use inside an ET tube, and those that use an ET tube delivery device. They represent a simple method for routine intubation and a promising rescue device for the difficult airway. These devices have varied learning curves. It is important to use these devices in simulations and routine intubations prior to using them as a rescue devices. These devices are useful for training healthcare personnel in the technique of orotracheal intubation in the prehospital and hospital setting. The use of a VL to intubate is much easier than using traditional DL, especially for novices.

Fiberoptic-Assisted Endotracheal Intubation Devices

Igor Kolesnikov, Gennadiy Voronov, and Ned Nasr

INTRODUCTION

Recent years have seen a rapid expansion in optical devices used to aid in endotracheal (ET) intubation. The devices that use fiberoptics begin near the distal end and transmit an image to be viewed at the proximal end. Some of these devices are variations on the "optical stylet" concept (Table 21-1). They consist of an eyepiece or other viewing mechanism attached to stylet of varying degrees of flexibility. A standard ET tube can be jacketed onto each device. The stylet can then be used as an adjunct to standard ET intubation or as a stand-alone device. These devices are being replaced by video laryngoscopes that are more versatile, easier to operate, and easily learned by a novice user. Most fiberoptic stylets and their variations are falling out of favor and are less often used today.

Traditional direct laryngoscopy requires alignment of the oral, pharyngeal, and laryngeal axes to visualize the glottis. It is not always possible to align these three axes despite mechanical manipulation. The major advantage of fiberoptic laryngoscopy devices is that they do not require the Emergency Physician to align the three airway axes, reduce the need for airway manipulation, and reduce potential traumatic forces on the airway (Table 20-1). Fiberoptic devices provide a superior view of the glottis when compared to traditional direct laryngoscopy. The lens of fiberoptic devices is within centimeters of the glottis and provides a wider angle of vision than the 15° of traditional direct laryngoscopy. The viewing port magnifies the view of the airway, making critical structures easier to visualize.

A generalized approach to using optical stylet-type devices will first be discussed, followed by the unique features of selected devices. This chapter reviews a representative number of device types currently available and commonly used in Emergency Departments (Table 21-1). A detailed discussion of video laryngoscopy is contained in Chapter 20. The intent of this chapter is not to describe every single product on the market.

TABLE 21-1 Some of the Commercially Available Fiberoptic Devices

Name	Manufacturer	Comments
AincA Video Stylet	Anesthesia Associates	2.4 inch rechargeable color monitor Can be used with a laryngoscope handle Fits ET tube (ETT) sizes ≥ 6.0 mm inner diameter
Air-Vu Plus Fiberoptic Stylet	Cookgas	Malleable Adjustable tube stop Can be used with a laryngoscope handle or battery light source Designed for use with Air-Q laryngeal mask Fits ETT sizes ≥ 5.5 mm inner diameter Oxygen insufflation port Rigid
Bonfils Retromolar Intubation Endoscope	Karl Storz Endoscopy	Can be used with battery-powered or portable light source Comes in two sizes (3.5 and 5.0 mm outer diameter) ETT must be 0.5 mm or greater in inner diameter size to fit oxygen insufflation port Rigid with a 40° curve Rugged and able to lift soft tissues out of the way Use with eyepiece or connect to DCI Video System
Clarus 30000-V Intubation Video System	Clarus Medical	5.0 mm outer diameter Attached LCD screen Can be used as a lighted stylet Fits ETT sizes ≥ 5.5 mm inner diameter Malleable rigid scope Red LED illumination provides better visualization
Levitan Scope	Clarus Medical	Fits ETT sizes ≥ 5.5 mm inner diameter Malleable rigid scope Oxygen insufflation port Preformed shape ("hockey stick") Tube stop Use in direct laryngoscopy or alone
Pocket Scope	Clarus Medical	Deflected tip allows nasal intubation Fits ETT sizes ≥ 4.0 mm inner diameter Flexible stylet Stylet wraps around to limit size
SensaScope	Acutronic Medical Systems	3 cm of tip steers Fits ETT sizes ≥ 6.5 mm inner diameter Lever moves tip 75° in sagittal plane Semirigid-shaped
Shikani Optical Stylet	Clarus Medical	Can use multiple light sources Comes in two versions (adult and pediatric) Fits ETT sizes 2.5–5.0 and 5.5 mm inner diameter Malleable rigid scope Oxygen insufflation port Preformed shape ("hockey stick") Tube stop Use in direct laryngoscopy or alone

INDICATIONS AND CONTRAINDICATIONS

Fiberoptic intubation devices can be used for adult and pediatric difficult (i.e., actual or anticipated) intubation, elective intubation, emergent intubation, and routine intubation. These devices can be used as "rescue devices" in cases of failed direct laryngoscopy. Patients with their head and neck immobilized, limited mouth opening, or morbid obesity or patients requiring awake intubation

or intubation while in a sitting position can benefit from intubation with these devices. These devices provide better visualization of the glottis, decreased cervical movement, and higher success rates in comparison to traditional direct laryngoscopy. These devices can be used to aid in the localization and removal of airway foreign bodies. There are no contraindications to using fiberoptic devices.

USING FIBEROPTIC INTUBATION DEVICES

There are some general guidelines to using fiberoptic intubation devices that will improve the Emergency Physician's success in their implementation. It is useful to understand the limitation of these devices. Fogging is a common problem. Fogging can be minimized by applying a medical-grade antifog solution to the lighted end of the instrument or warming the distal tip by placing it in a warm blanket or warmed saline solution. Any fluid (e.g., blood, secretions, or vomitus) in the oropharynx will limit the usefulness of these devices. Suction any fluid and debris from the oropharynx prior to device insertion. Use care to avoid touching the mucosal surface with the distal tip of the device. Encountering the mucosa can cause "pink out" and promote fogging of the device, both of which will impair visualization. Fiberoptic intubation devices cannot be used to separate tissues. They should follow an open channel created by a standard laryngoscope or by manual distraction of the patient's jaw.¹ Small movements are magnified by these devices. Proceed slowly and identify known landmarks as the device is navigated from the mouth to the glottic opening. Getting lost in a field of pink mucosa is best overcome by slowly backing the device out until known landmarks are visualized and identified, and then slowly re-advancing the device along a path of familiar anatomy.

LEVITAN SCOPE

The Levitan Scope (Clarus Medical, Minneapolis, MN) was created by Dr. Richard Levitan (**Figure 21-1**). He is an Emergency Physician, a noted airway educator, and an innovator. The Levitan Scope differs from other devices in this chapter in that it is shorter and requires the ET tube to be cut to a length of approximately 28 cm. Cutting the ET tube is an inconvenient step. Doing so makes the working length of the scope shorter and wielding the device easier. The scope is equipped with a side port that allows for oxygen insufflation. The distal end of the device is flexible and allows it to be bent to the specific needs of the scenario. It is powered by a detachable battery-operated light source or with a standard green line fiberoptic laryngoscope handle. It is relatively affordable compared to other

FIGURE 21-1. The Levitan Scope. (Photo courtesy of Clarus Medical, Minneapolis, MN.)

devices. Much of the intubation strategy described for the Levitan Scope is generalizable to other optical stylets. The techniques and strategies are summarized from a publication by the inventor.²

PREPARATION

Prepare the scope for use. Liberally lubricate the scope with water-soluble lubricant. **Do not get lubricant on the lens.** Apply an ET tube of 6.0 mm or larger over the shaft. **The tip of the scope should be approximately 1 cm from the end of the ET tube.** Connect the side port to oxygen tubing. Turn on the oxygen source to provide a flow rate of 5 to 10 L/min. This flow rate allows for oxygen insufflation and aids in keeping the lens clear. The manufacturer recommends bending the distal tip to approximately 35° in the straight-to-cuff fashion. Attach the light source, either a miniature LED light source or a green line fiberoptic laryngoscope handle.

TECHNIQUE

The Levitan Scope was designed for incorporating the option of fiberoptic assistance into every intubation attempt. The scope will simply act as a stylet in most cases where landmark visualization is feasible with standard laryngoscopy. Additional confirmation can be made by visualizing the tracheal rings via the eyepiece once ET intubation is achieved.

The Levitan Scope jacketed with an ET tube can be used for fiberoptic intubation when ET intubation is not possible by direct laryngoscopy. Obtain the best visualization of the airway anatomy possible using the traditional laryngoscope. At least the tip of the epiglottis should be visible. Introduce the scope into the mouth under direct vision. Advance the scope until its tip is positioned approximately 1 cm superior to the epiglottis. It may be helpful to rest the device against the patient's dentition at the right corner of the mouth to maintain this position. Avoid touching the distal tip of the scope against the mucosa to prevent "pink out" and fogging.

Switch from direct visualization to fiberoptic viewing via the device's eyepiece. Identify the airway structures. Slowly advance and direct the tip of the scope under the epiglottis. Continue to advance the tip of the device into the glottic opening. Pivoting the device toward the Emergency Physician will direct the tip of the scope anteriorly toward the glottic opening if the device is resting at the right corner of the patient's mouth. Confirm proper placement by visualizing the tracheal rings through the eyepiece.

Remove the laryngoscope once the tip of the Levitan Scope with the jacketed ET tube has been advanced through the vocal cords and into the trachea. Advance the ET tube by rotating it off the stylet in a counterclockwise fashion. Rotating the ET tube while advancing it helps to prevent the beveled edge from catching on the tracheal rings. Securely hold the ET tube. Remove the Levitan Scope and secure the ET tube.

The Levitan Scope can be used without a laryngoscope, although it may require more practice to become adept at this technique. Prepare the scope as described above, with the exception that the distal 3 to 4 cm should be bent to approximately 70°. Grasp the patient's jaw and tongue in the left hand and lift to create an open channel for the scope. Insert and advance the scope in the midline while avoiding contact with the mucosal surfaces. Look through the eyepiece and advance the device with the ET tube through the glottic opening.

VIDEO RIFL

The Video Rigid Intubating Fiberoptic Laryngoscope or Video RIFL (AI Medical Devices Inc., Williamston, MI) is unique among the optical stylets in that it has a flexible tip that can be manipulated with a trigger at the handle-end of the device (Figure 21-2). There

FIGURE 21-2. The Airway RIFL. (Photo courtesy of AI Medical Devices Inc., Williamston, MI.)

were originally two models available, the Airway RIFL and the Video RIFL. The Video RIFL replaced the eyepiece of the Airway RIFL with a small LCD screen. The Nasal RIFL stylet attaches to the device and allows nasal intubation. The high-resolution LCD screen rotates 180° to provide visualization from any angle. The Video RIFL has a unique tip that articulates up to 135° to navigate obstructions. The device can be used as a stand-alone device or as an adjunct to standard laryngoscopy. It can be used to facilitate intubation through many supraglottic airway devices (e.g., the Air-Q or I-gel). The primary disadvantages of this device are the cost, the relative length of the device, and that it is top-heavy. Being top-heavy and the length may prove cumbersome for users of shorter stature.

The two-sided RIFL Blade can be used in conjunction with the Video RIFL. It is a disposable, single-use, plastic blade the use of which is optional. The RIFL Blade is inserted into the midline of the patient's mouth and lifted to elevate the tongue, open the airway, and provide a path to the glottis.

PREPARATION

Inspect the Video RIFL for any damage. Turn it on. Liberally lubricate the stylet portion of the device with a water-soluble lubricant. Place a 6.5 mm or larger ET tube onto the stylet. The current model does not accommodate ET tubes less than 6.5 mm. A smaller pediatric version is being developed. Set the tube stop so that the tip of the stylet is just inside the distal end of the ET tube.

TECHNIQUE

The device can be used as a stylet to introduce the ET tube into the trachea as an adjunct to standard direct laryngoscopy if the glottic opening can be easily visualized using a standard laryngoscope.

Insert and advance the device as described for the Levitan Scope if the laryngeal structures are not well visualized with direct laryngoscopy. Attempt to visualize the epiglottis through the eyepiece or the LCD screen of the Video RIFL. Advance the device under the epiglottis and through the vocal cords. Squeeze the trigger-like handle of the Video RIFL to direct the tip of the instrument. Release the handle once the tip of the device passes through the vocal cords to facilitate advancement of the ET tube from the device. Advance the ET tube into the trachea. Withdraw the device and secure the ET tube. Confirm proper ET placement.

The Video RIFL can be used as a stand-alone device without the aid of a laryngoscope. Grasp the patient's mandible and tongue in the left hand and manually distract it. Insert the Video RIFL into the patient's mouth with the long axis of the device parallel to the palate. Look through the eye piece or at the LCD screen to visualize the airway structures. Flex the tip of the device to visualize the vocal cords. Advance the Video RIFL through the vocal cords. Complete the remainder of the procedure as described above.

AIR-VU PLUS FIBEROPTIC SCOPE

The Air-Vu Plus Fiber Optic Scope (Mercury Medical, Clearwater, FL) is an optical stylet designed specifically for aiding in fiberoptic ET tube placement through the Air-Q supraglottic airway (Mercury Medical, Clearwater, FL). It is a rigid device with a curved tip designed to fit the shape of the Air-Q (**Figure 21-3**). The Air-Vu Plus can be used with a compact LED light source or a standard green line fiberoptic laryngoscope handle. The device can be used as an optical stylet or as a stand-alone device like the Levitan Scope. The primary advantage of the Air-Vu Plus versus other devices is its compatibility with the Air-Q. The primary disadvantage is the rigidity of the device and the fixed curve of the shaft, both of which can make advancement of the device and the ET tube difficult.

SHIKANI OPTICAL STYLET

The Shikani Optical Stylet or S.O.S. (Clarus Medical, Minneapolis, MN) is unique among the optical stylets in that it comes in both pediatric and adult sizes (**Figure 21-4**). The S.O.S. can be used with a variety of light sources (e.g., its own specific handle, a green line laryngoscope handle, or a fiber optic cable attached to a remote light source). The S.O.S. is malleable and can be shaped into a 70° to 80° angle at the tip for use as a stand-alone device or a 30° angle when used as an adjunct to standard direct laryngoscopy. The S.O.S. can be attached to oxygen tubing to allow insufflation of oxygen at 5 to 10 L/min. Intubation is achieved like other optical

FIGURE 21-3. The Air-Vu Plus Fiber Optic Scope. (Photo courtesy of Mercury Medical, Clearwater, FL.)

FIGURE 21-4. The Shikani Optical Stylet. (Photo courtesy of Clarus Medical, Minneapolis, MN.)

stylets. Advantages of the S.O.S. include the availability of adult and pediatric sizes, its malleability, less dental trauma, and the option of providing oxygen insufflation.³ There are several case reports of its successful use in children.^{4,5} The disadvantages are primarily related to its length, which makes coordination of intubation difficult for some users.

BONFILS RETROMOLAR INTUBATION ENDOSCOPE

The Bonfils Retromolar Intubation Endoscope (Karl Storz Endoscopy-America, El Segundo, CA) is simple in appearance (**Figure 21-5**).⁶ It can accommodate a 6.5 mm or larger ET tube and has an adjustable tube stop. It can be equipped with either an eyepiece or an adapter to couple with a monitor. It allows for oxygen insufflation via a side port. The curvature at the tip of the scope is fixed.

Intubation with the Bonfils Retromolar Intubation Endoscope is like other optical stylets with or without the aid of a standard laryngoscope. In one study, 103 of 107 patients with unanticipated difficult airways were successfully intubated with this device, with 80% intubated without the aid of a laryngoscope.⁷ The other 20% of patients were intubated with a Macintosh blade and the Bonfils scope. A study reports the device's success in the awake intubation of five patients with challenging airways.⁸ It can be difficult to maneuver this device into proper position under the epiglottis despite having higher success rates than traditional direct laryngoscopy.⁹

BULLARD LARYNGOSCOPE

The Bullard laryngoscope (Gyrus ACMI, Southborough, MA) is a device that is a fusion product between video laryngoscopes and optical stylets (**Figure 21-6**). It is an old device that is being replaced by more advanced video laryngoscopes. It can still be found in clinical practice. The Bullard laryngoscope provides superior views with less cervical spine movement than other laryngoscopes and video laryngoscopes.¹⁰

FIGURE 21-5. The Bonfils Retromolar Intubation Endoscope. (Photo courtesy of Karl Storz Endoscopy-America, El Segundo, CA.)

FIGURE 21-7. Three versions of the Bullard laryngoscope. From left to right: the pediatric model, the pediatric long model, and the standard model.

The Bullard is a rigid laryngoscope that combines a curved blade with fiberoptic visualization into a simple and easy-to-use handheld unit (**Figures 21-6 and 21-7**). The proximal handle contains an 11 French or 3.7 mm working port, a port to attach the light source (e.g., traditional laryngoscope handle or a fiberoptic laryngoscope handle), and a visualization port (**Figure 21-7**). The third or working port allows oxygen insufflation, suctioning, administration of pharmaceuticals, or the passage of a guidewire to promote tracheal intubation.^{11,12} The curved blade is similar in shape to a Macintosh blade. A fiberoptic bundle allows visualization of the vocal cords and tracheal intubation without a direct line of sight.

The Bullard laryngoscope is available in three sizes (**Figure 21-7**). The device is handheld, readily portable, self-contained, and operated as quickly as a traditional laryngoscope with a Macintosh blade. The ability to visualize the vocal cords without aligning the oral, pharyngeal, and laryngeal axes allows successful intubation with a minimum of cervical spine movement.¹¹⁻¹⁶

PREPARATION

Assemble the Bullard laryngoscope when the possible need for airway intervention is recognized. The working port can be fitted with a three-way stopcock to provide intermittent suction and oxygen insufflation. Attach a traditional laryngoscope handle as the light source. A fiberoptic light source with the required adapter may be used to provide illumination. Lubricate the lower half of the intubating stylet with a water-soluble lubricant. Attach the stylet to the fiberoptic bundle, between the eyepiece and the handle, on the right side of the laryngoscope. Select and load the appropriate-size ET tube onto the intubating stylet. **The tip of the stylet should extend 0.5 cm past the distal end of the ET tube.** Place the tip of the stylet beneath the flange of the blade. It is recommended, but not required, that a disposable plastic blade extender be placed on the tip of the metal blade for adult intubations.

TECHNIQUE

Stand at the head of the bed. Open the patient's mouth to a minimum of 0.6 cm between the upper and lower incisors. Grasp the handle of the Bullard laryngoscope parallel to the patient and toward the patient's feet (**Figure 21-8A**). Insert the blade into the midline of the mouth. Lift the laryngoscope handle upward (**Figure 21-8B**). Slightly elevate the Bullard laryngoscope to lift the tongue (**Figure 21-8C**). The blade will follow the contour of the tongue and pharynx with minimal effort.

FIGURE 21-6. Anatomy of the Bullard laryngoscope.

FIGURE 21-8. Intubating with the Bullard laryngoscope. **A.** Inserting the laryngoscope. **B.** Rotation of the handle 90° properly positions the laryngoscope. **C.** Slight elevation of the laryngoscope moves the tongue and epiglottis out of the visual axis. **D.** Advancement of the endotracheal tube under direct visualization. **E.** Removal of the Bullard laryngoscope. It is first rotated 90° toward the patient's feet (*curved arrow*), then lifted out of the mouth (*straight arrow*).

The blade of the Bullard laryngoscope will elevate the epiglottis (**Figures 21-8C and D**). Visualize the airway through the fiberoptic port (**Figure 21-8D**). The view can be focused by turning the eyepiece. The blade can be repositioned by backing it out toward the posterior pharynx to catch the epiglottis if the blade is not beneath the epiglottis. Suction through the working port if blood, debris, or secretions limit the view. Advance the ET tube under direct visualization when the vocal cords are visualized (**Figure 21-8D**). Secure the ET tube at the patient's teeth with the nondominant

hand. Remove the Bullard laryngoscope with the dominant hand by reversing the technique of insertion (**Figure 21-8E**).

The Bullard laryngoscope allows for other strategies to aid in ET intubation. The stylet has a central opening of 4.5 mm in the adult model and 3.6 mm in the pediatric long model, which can be used to pass an intubating guidewire through the vocal cords.¹² An intubating guidewire may be passed through the working port and through the vocal cords. In either case, insert the guidewire, remove the Bullard laryngoscope, and pass the ET tube over the guidewire

and into the trachea. It is possible to pass an ET tube with a standard malleable stylet. The styletied ET tube can be bent into a shape approximating that of the Bullard laryngoscope.

Problems specific to the Bullard laryngoscope include the inability to visualize the vocal cords. Confirm that the laryngoscope is in midline. Reposition it by moving the blade into the posterior pharynx and attempt to capture the epiglottis if the blade is above the epiglottis and the view obscured. Use a disposable plastic blade extender to avoid this difficulty. Suction through the working port if the view is obscured by debris. Visualize the stylet with the loaded ET tube through the scope. It may have slipped underneath the blade if not visualized. Reposition the stylet and ET tube without removing the laryngoscope.¹² Extension of the stylet too far beyond the ET tube may cause abrasions, bleeding, and lacerations to the walls of the oral cavity, oropharynx, and laryngopharynx. These can be prevented with proper assembly of the Bullard laryngoscope.

OTHER DEVICES

Other fiberoptic devices are available (Table 21-1 and Figures 21-9 through 21-11). These devices are used like the above devices. They also are not used as often as video laryngoscopes.

COMPLICATIONS

Most of the complications associated with fiberoptic devices mirror those of ET intubation (Chapter 18). These include failure to intubate, esophageal intubation, right mainstem bronchus intubation, and the hemodynamic consequences of intubation. The most common difficulty encountered in ET tube passage is impaction of the ET tube on the right arytenoid cartilage. This obstacle can be overcome by directing the device slightly toward the patient's left side. Alternatively, rotate the ET tube until the bevel is facing the viewing channel.

VIDEO LARYNGOSCOPES

Video laryngoscopes have received wide acceptance in clinical practice over the past 8 to 10 years (Chapter 20). They allow relatively stress-free intubation on challenging airways by even fairly inexperienced clinical personnel. Many of these devices allow recording

FIGURE 21-10. The AincA Video Stylet. (Photo courtesy of Anesthesia Associates, San Marcos, CA.)

capabilities that might be important due to the increased malpractice litigations related to substandard airway management. They are becoming more and more common. These devices are considered the next-generation scopes that followed the optical stylets and the

FIGURE 21-9. The Acutronic Sensascope. (Photo courtesy of Acutronic Medical Systems AG, Switzerland.)

FIGURE 21-11. The Clarus Pocketscope. (Photo courtesy of Clarus Medical LLC, Minneapolis, MN.)

Bullard. They do not incorporate a stylet as part of their integral design. Video laryngoscopes may fall under standard blade styles, angulated blade styles, and anatomically shaped channeled design.¹⁷

The design allows the video laryngoscope to be inserted in the midline without sweeping the tongue laterally. Video laryngoscopes allow the Emergency Physician an option of using them as a direct laryngoscope without the video display. The benefits of these devices over standard laryngoscopes are limited, but they present good teaching capabilities since several providers can observe the patient's airway and ET tube placement.¹⁷ Video laryngoscopes that have reusable blades are usually more difficult to maintain than the conventional direct laryngoscopes. Their maintenance requires extra time and costs that cannot always be justified. The user essentially pays "per use" with disposable blades, which makes them expensive. These extra costs may be justified in anticipated difficult airway cases.

Video laryngoscopes are largely very safe. Injury to airway structures is due to blind insertion of ET tubes with visualization on the screen only, in other words blind insertion. There is a blind spot from the time the tube is orally inserted until the tip is visualized on the screen. This seems to be the most vulnerable time for injury. This can largely be avoided by what has been described the "look up–look down" approach.¹⁷ The basic premise is to directly visualize the scope and ET tube (i.e., look down) enter the oral cavity, indirectly visualizing the vocal cords and the entry of the ET tube into the glottic opening (i.e., look up). Another mechanism of airway injury has been attributed to the stylet itself. This can be partially avoided by withdrawing the stylet soon after entering the glottis and before advancing the ET tube further.

SUMMARY

A variety of fiberoptic devices are available to help indirectly visualize the vocal cords and aid in intubating the trachea. The devices have a variety of features including malleable stylets, articulating tips, and differing lengths. The devices can be shaped for differing applications (e.g., used with and without a laryngoscope or to be inserted through a supraglottic airway). The devices feature different visualization capabilities (e.g., fixed eyepiece or optional video screen). Fiberoptic devices offer alternative techniques for managing the airway. Every Emergency Department should have at least one of these devices available to aid in intubation when direct laryngoscopy is difficult or fails.

Endotracheal Tube Intubating Introducers and Bougies

Marco Mikhael, Gennadiy Voronov, and Ned Nasr

INTRODUCTION

The endotracheal tube introducer (also known as an introducer) and a tracheal tube bougie (also known as the bougie) have been effective, easy-to-use, and inexpensive adjuncts to difficult airway management for many years (**Figure 22-1**).¹ Although newer devices such as the fiberoptic bronchoscopes and the video laryngoscopes are becoming more frequently used in the Emergency Department (ED) in difficult airway situations, skills pertaining to bougie insertion should be developed and maintained.² They can be valuable if other intubating modalities are not readily available or the airway cannot be secured with direct laryngoscopy. It is recommended that a bougie be readily available in every ED.

FIGURE 22-1. Tracheal tube introducers and bougies. From top to bottom: Eschmann introducer, Frova intubating introducer, Muallem endotracheal tube stylet, S-guide with universal connector, Muallem endotracheal tube introducer, Rivier airway introducer, Cook airway exchange introducer 14 French, Cook airway exchange introducer 8 French, Cook tube exchanger, and Aintree intubation catheter. (Used with permission from reference 1.)

Airway management in the ED often occurs in an unpredictable and uncontrolled environment, sometimes with the patient arriving unannounced.³ Difficult intubation should be always anticipated and prepared for.³ The American Society of Anesthesiology defines a difficult intubation as an inability to properly insert an endotracheal tube with traditional direct laryngoscopy in three attempts or if intubation takes longer than 10 minutes.⁴ Difficult intubations usually reflect poor glottic visualization during direct laryngoscopy. A four-grade classification system by Cormack and Lehane describes the views of the laryngeal inlet during laryngoscopy.⁵ The exact incidence of difficult-to-intubate patients in the ED is difficult to extrapolate, with estimates ranging from 6% to 11%.^{6,7}

Difficulties arise when the vocal cords cannot be fully visualized due to airway distortion (e.g., edema, expanding hematomas, radiation, surgery, or trauma), airway masses, anatomic variations, limited neck mobility due to cervical spine fractures and cervical collars, deformities of the head and neck, orofacial injuries, or oropharyngeal blood and secretions. One study reported that the vocal cords could not be visualized in 22% of patients wearing a cervical collar.⁸ **This failure to visualize the glottis can make intubation difficult or impossible. The intubating introducer, tracheal tube introducer, or bougie can be a good rescue device in these situations.** The main advantage of these devices is the angled or coude tip that can be aimed anteriorly and advanced under the epiglottis and into the trachea. Intubation with one of these devices was first described by MacIntosh in 1949.⁹ The device he used was a 60 cm long, 15 French, elastic catheter with a J or coude tip that was bent 40° at the distal end.

The bougie or introducer is used to facilitate difficult intubation. It is a thin, long, cylindrical rod composed of rubber or plastic. Despite sometimes being called “gum elastic bougies,” they are not composed of gum, not composed of elastic, and not true bougies (i.e., dilators).¹⁰ They are inexpensive, with most costing less than \$20.00 each. They are available in numerous adult and pediatric sizes, various degrees of flexibility, and are with a variety of ports and/or devices. They are flexible enough to allow an endotracheal tube to freely pass over them or to be inserted through a supraglottic airway device, yet stiff enough to be easily maneuvered and advanced into the airway.

The bougie or introducer should not be confused with the more rigid malleable stylet, which is inserted into an endotracheal tube and used to alter its shape prior to intubation. Unlike the stylet, a bougie or introducer is usually inserted independently of the endotracheal tube and is used as a guide. The bougie is considerably softer, more malleable, and blunter than a stylet. The insertion of a bougie is a relatively atraumatic procedure.¹¹

This chapter reviews the general principles for using tracheal tube introducers, intubating introducers, and bougies and reviews some of the more commonly available devices. The terms *tracheal tube introducers*, *intubating introducers*, and *bougies* are often used interchangeably. The remainder of this chapter uses the general term *bougie* unless some other term is specific to a manufacturer's device.

INDICATIONS

The bougie is intended to facilitate endotracheal intubation in patients when the epiglottis is visible but visualization of the glottis is difficult or inadequate (i.e., grade 3 Cormack-Lehane view) despite external laryngeal manipulation and optimal patient positioning.¹² The most frequent indication for the use of a bougie is the inability to intubate endotracheally using traditional direct laryngoscopy. It can also be used for “routine intubations.” The narrower and more flexible bougie, compared to an endotracheal tube, can easily be inserted into the trachea when the glottis is visualized

during direct laryngoscopy and the endotracheal tube is advanced over the bougie. A bougie can be inserted directly into the trachea or through a supraglottic airway device to facilitate endotracheal intubation. A bougie may be inserted when the glottic opening is visible but the endotracheal tube will not pass through the vocal cords. The bougie serves as a placeholder in these cases and avoids the need to remove the laryngoscope and re-perform direct laryngoscopy when the bougie is available. The use of a bougie to intubate the trauma patient may result in less cervical spine motion than traditional direct laryngoscopy.¹³ Long bougies, at least 70 cm, can also be used as an endotracheal tube exchanger.

CONTRAINDICATIONS

There are no absolute contraindications to the use of a bougie. Bougies should be used with caution, if at all, in patients with airway trauma because they can result in additional injury and hemorrhage to the airway structures, perforation (e.g., piriform fossa, trachea, bronchus, or esophagus), or barotrauma.¹⁴⁻¹⁶ Bougies are unlikely to be beneficial when no part of the airway is visible (i.e., grade 4 Cormack-Lehane view) and are relatively contraindicated. Another relative contraindication is its use in children. The lack of calcification and mineralization of the tracheal rings makes it difficult to sometimes differentiate between the trachea and esophagus.

EQUIPMENT

- Endotracheal tubes, various sizes
- 10 mL syringe
- Water-soluble lubricant or anesthetic jelly
- Wire stylet, malleable type
- Laryngoscope handle
- Fresh batteries for the laryngoscope
- Laryngoscope blades, various sizes and shapes
- Supplemental oxygen with appropriate tubing and connectors
- Nonrebreather oxygen masks, various sizes
- Wall suction with appropriate tubing
- Yankauer suction catheter
- Bag-valve device, various sizes
- Oral airways, various sizes
- Nasal airways, various sizes
- Benzoin adhesive
- Tape
- Pulse oximeter
- Cardiac monitor
- Automatic sphygmomanometer
- End-tidal carbon dioxide (CO₂) monitor or device
- Cricothyrotomy backup tray
- Crash cart
- Resuscitation medicines
- Personnel (e.g., respiratory technician, medication nurse, in-line stabilization assistant, recorder)
- Medications (i.e., premedications, induction, anesthetics, paralytics)
- Endotracheal tube introducer or bougie

Some of the more commonly used devices in the ED are described below. Other commercially available bougies also exist (**Table 22-1**).

TABLE 22-1 Some of the Commercially Available Intubating Introducers and Bougies

Name	Manufacturer	Length(s) (cm)	Size(s) (French)	Comments
Aintree Intubation Catheter	Cook Medical	56	19	Hollow with two holes at distal end Allows passage of fiberoptic bronchoscope Rapi-Fit adapters allow bag-valve and jet ventilation Allows ventilation while exchanging endotracheal tube (ETT) and supraglottic airway (SGA)
Arndt Airway Exchange Catheter	Cook Medical	50 65 78	8 14	Hollow with multiple side holes at distal end Allows passage of fiberoptic bronchoscope Rapi-Fit adapters allow bag-valve and jet ventilation Allows ventilation while exchanging ETT and SGA
Cobra Introducer	Occam Design	60 (telescopes to 73)	15	Straight tip Fits ETT sizes 6–11
Cobralet	Occam Design	60	15	Coudé tip Hollow with side holes at distal end Allows ventilation Fits ETT sizes 6–11
Cook Airway Exchange Catheter	Cook Medical	43 83 100	8 11 14 19	ETT exchanger but can be used as bougie Rapi-Fit adapters allow bag-valve and jet ventilation Soft-tip model minimizes trauma to airway
CoPilot VL Single-Use Bougie	Magaw Medical	60	14	Coudé tip Fits ETT \geq 6.0 mm inner diameter
Frova Intubating Introducer	Cook Medical	35 65	8 14	Angled tip Fits ETT \geq 3.0 mm inner diameter Hollow with side holes at distal end Comes with metal stiffening cannula Rapi-Fit adapters allow bag-valve and jet ventilation
Introes Pocket Bougie	BOMimed	60	14	Malleable Coudé tip Comes curved with shape memory Fits ETT \geq 5.0 mm inner diameter
Muallem ET Tube Stylet	VBM Medizintechnik	40 65	8 12 14	Atraumatic soft coudé tip
Pocket Introducer	VBM Medizintechnik	65	15	Folded to 20 cm to save space Unfolds fast
Portex Venn Tracheal Tube Introducer	Smith's Medical	60	15	Coudé tip Sterilizable and reusable
Rhinoguard	Davis Medical	25.4 35.5	N/A	Designed for nasal intubation Can be used as a bougie Fits sizes 3–8 ETT
Single-Use Bougie	Smith's Medical	70	15	Coudé tip Hollow allows bag-valve and jet ventilation
VBM Introducer	VBM Medizintechnik	65	15	Coudé tip Hollow allows bag-valve and jet ventilation
VBM S-guide	VBM Medizintechnik	65	15	Atraumatic coudé tip Hollow allows bag-valve and jet ventilation
VBM Tube Exchanger	VBM Medizintechnik	80	11 14 19	ETT exchanger but can be used as bougie Hollow allows oxygenation

ESCHMANN TRACHEAL TUBE INTRODUCER

The Eschmann tracheal tube introducer was formerly known as the gum elastic bougie. Reusable, or multiple-use, and single-use disposable versions are available. The Eschmann multiple-use tracheal tube introducer was introduced into clinical practice in 1973. The Portex single-use introducer (Smiths-Medical, Dublin, OH) became available in 1997 and replaced the Eschmann Introducer. It is a 60 cm long, 15 French, flexible device with a J-angle at its distal tip (**Figure 22-2**). During use, the multiple-use introducer forms a curve toward its distal end. The single-use introducer is more rigid and is thus more likely to cause trauma.¹⁷ It does not maintain a curved shape when bent, and it has a significantly lower tracheal

placement rate in simulated grade 3 Cormack-Lehane views.¹⁸ The multiple-use device retained the curved shape for longer compared with the single-use device.

FROVA INTUBATING INTRODUCER

The Frova Intubating Introducer (Cook Medical Inc., Bloomington, IN) was introduced into clinical practice in 1998. The Frova is a single-use device able to maintain the desired curvature—a feature shared with the Eschmann multiple-use introducer.¹⁹ It is a flexible, hollow, radiopaque polyethylene plastic catheter with centimeter markings and a blunt curved tip (**Figure 22-3**). It is available in two sizes, the 14 French version for 6.0 mm and larger endotracheal

FIGURE 22-2. The Portex Tracheal Tube Introducer. (Photo courtesy of Smiths Medical, Dublin, OH.)

tubes and the 8 French version for 3.0 mm and larger endotracheal tubes. It is packaged with a removable metal cannula that stiffens the device except for the distal tip. The advantage of the metal cannula is that it can be bent to change the shape of the Frova and make it easier to advance. The disadvantages of the metal cannula are that

FIGURE 22-3. The Frova Intubating Introducer with Rapi-Fit adapter. From left to right: the proximal end with the Rapi-Fit adapter, the body with centimeter markings, and the distal end. (Photo courtesy of Cook Medical Inc., Bloomington, IN.)

FIGURE 22-4. The SunMed Bougie. From top to bottom: 10 French coudé tip pediatric version, 15 French straight tip adult version, and the 15 French coudé tip adult version. (Photo courtesy of SunMed, Largo, FL.)

it makes the Frova more rigid and harder to maneuver and potentially increases airway soft tissue trauma. Products with the suffix “-FII” also include a stiffening cannula and two Rapi-Fit adapters for connection to a ventilatory device. Products with the suffix “-FI” include two Rapi-Fit adapters for connection to a ventilatory device, but no stiffening cannula. The adapter can be used to ventilate the patient and confirm proper tracheal placement before advancing the endotracheal tube. It takes only 15 seconds to attach an aspirating esophageal detector device to the adapter and confirm its position.²⁰

SUNMED BOUGIE

The SunMed Bougie (SunMed, Largo, FL) is made of a blend of low- and high-density polyethylene for optimal stiffness and has depth calibration markings. It is 70 cm long and available as a 10 French pediatric size or a 15 French adult size (**Figure 22-4**). Three versions of these devices are available: the original, the malleable, and the ported version. The original adult version is available with a straight or curved tip and fits 4.0 to 11.0 mm endotracheal tubes. The original pediatric version is only available with a curved tip. The malleable version has a color-coded stopper and fits 6.0 to 11.0 mm endotracheal tubes. The ported version allows for the insufflation of oxygen and gas sampling. It is available only in the 15 French size. It uses a blend of low- and medium-density polyethylene for optimum firmness, and its depth is calibrated in centimeters. A study comparing the SunMed, Portex, Greenfield, and Eschmann bougies demonstrated that Emergency Physicians had better success rates using the SunMed and Greenfield devices, but they had a low preference for the Greenfield bougie.²¹

GREENFIELD FLEX-GUIDE ET TUBE INTRODUCER

The Flex-Guide ET Tube Introducer (Greenfield Medical Sourcing Inc., Austin, TX) is a 60 cm long polyethylene tube that is available in a 15 French (i.e., 5.0 mm) diameter for adults and a 10 French (i.e., 3.3 mm) diameter for children (**Figure 22-5**). The ends of the Flex-Guide are smooth and rounded with a bend 2 cm from the distal end, resulting in a 30° coudé tip. The tubing is flexible and can be straightened or bent as required. The adult Flex-Guide has a black band marking 37 cm from its proximal end (**Figure 22-5**) to help determine correct placement depth. The pediatric Flex-Guide has markings every 10 cm (**Figure 22-5**). The Flex-Guide is similar to the Eschmann or Portex bougie, only more economical. This device has been used in the ED to intubate difficult airways.²²

FIGURE 22-5. The Greenfield Flex-Guide Endotracheal Tube Introducer adult version (above) and pediatric version (below). (Photo courtesy of Greenfield Medical Sourcing Inc., Austin, TX.)

FIGURE 22-6. The Aintree Intubation Catheter. From left to right: the proximal end with the Rapi-Fit adapter, the body with centimeter markings, and the distal end. (Photo courtesy of Cook Medical Inc., Bloomington, IN.)

AINTREE INTUBATION CATHETER

The Aintree Intubation Catheter (Cook Medical Inc., Bloomington, IN) was designed to be used with a fiberoptic bronchoscope (**Figure 22-6**). It is packaged with a Rapi-Fit Adapter that allows ventilation through the device and air exchange through the multiple distal side ports. The Aintree is only available in one size and for use with endotracheal tubes greater than 7.0 mm in diameter. It may also be used as a bougie without the fiberoptic bronchoscope. It is generally not used as a bougie due to it being hollow, flexible, straight, and lacking the flexed tip of a typical bougie.

POCKET BOUGIES

These are single-use catheters that can be folded and placed in an emergency bag. The Introes Pocket Bougie (BOMImed, Winnipeg, Manitoba, Canada) is a 60 cm long malleable bougie. It is made of a special blend of Teflon to balance the rigidity and offer soft tissue protection (**Figure 22-7**). The diameter of 14 French (i.e., 4.7 mm) accommodates size 5.0 endotracheal tubes and greater. It can be used with direct laryngoscopy or video laryngoscopy. It has a unique curvature that follows the natural airway. Its flexibility allows manipulation of the distal coude tip for anterior airways. The Tactiglide technology facilitates tactile sensation.

Another pocket introducer is manufactured by VBM Medizintechnik in Germany. It is 65 cm long and 15 French in diameter with a coude tip. It can be folded to only 20 cm and unfolds to 65 cm within seconds.²³

ENDOTRACHEAL TUBE EXCHANGERS

The use of an endotracheal tube exchanger to facilitate orotracheal intubation similar to a bougie is not recommended. These devices

FIGURE 22-7. The Introes Pocket Bougie.

are straight, very flexible, thin-walled, and hollow tubes. Their flexibility makes it difficult for them to be advanced into the trachea and they more often enter the esophagus. These thin-walled hollow tubes become even more flexible when inserted and warmed by the patient's body temperature.

PATIENT PREPARATION

The patient preparation is the same as that for orotracheal intubation (Chapter 18). The patient should be appropriately monitored with electrocardiography (ECG), end-tidal CO₂ monitoring, noninvasive blood pressure cuff, and pulse oximetry. As for any situation where airway manipulation is to occur and the patient's protective airway reflexes are blunted or ablated, a fully functioning suction apparatus with a variety of catheters must be immediately available. Place the patient supine with their head in a neutral position.

Place the patient, with a normal neck, in the "sniffing" position, with their head extended at the atlantooccipital joint while the neck is relatively flexed. A folded towel under the occiput helps to gently raise and tilt the head back into the proper position in adults. An appropriate-size shoulder roll should be placed in pediatric patients. **Correct positioning is probably the most important preparation of the patient.** Dentures should be left in place temporarily, as they help to stabilize the mouth and prevent occlusion during preoxygenation and bag-valve-mask ventilation.

TECHNIQUES

OROTRACHEAL INTUBATION

The bougie can be used in anticipation of a difficult airway or when a difficult airway is encountered and direct laryngoscopy is not successful. Instruct an assistant to ventilate the patient with a bag-valve-mask device. Liberally lubricate the bougie with water-soluble lubricant if there is a tight fit of the endotracheal tube because it allows the latter to slide easily over the bougie. If there is no tight fit, the lubricant can make the bougie difficult to grasp and control. A silicone spray, if available, may be used instead of the water-soluble lubricant. Insert the laryngoscope loaded with either a Macintosh or Miller blade. Elevate the laryngoscope and attempt to visualize the

epiglottis and vocal cords. Insert the bougie through the vocal cords and into the trachea if the vocal cords are visualized in part or completely. Care should be taken to keep the tip of the bougie pointing anteriorly and in the midline. The tracheal rings may not be appreciated if the bougie rotates significantly. Forceful insertion must be avoided as this can result in an iatrogenic airway injury such as bleeding and perforation.

Attempt to pass the bougie under the epiglottis with the curved distal tip facing anteriorly if the vocal cords are not visualized (Figures 22-8A and B). Slowly and carefully advance the bougie distally toward the trachea. The bougie will slightly jump or bounce as its tip is advanced over each tracheal ring (Figure 22-8C). This is sometimes referred to as the “palpation of a click” as the tip passes

over each tracheal ring. Advance the bougie approximately 10 to 15 cm into the trachea (Figure 22-8D). Securely hold the bougie in place. Do not remove the laryngoscope after the bougie is placed within the trachea. The laryngoscope will continue to elevate the tongue and allow easier passage of the endotracheal tube.

There are several signs that signify proper bougie placement within the trachea. If the bougie is unable to be advanced more than 40 cm from the patient’s lips in an adolescent or adult, or more than 24 cm in the child, it is likely caught at the carina or bronchus as the airway narrows. This is sometimes referred to as the “hold-up” sign. The “hold-up” sign in addition to the palpation of “clicks” as it is inserted confirms proper tracheal positioning of the bougie.²⁴ If the bougie freely advances more than 40 cm from the adolescent

FIGURE 22-8. Intubation using a bougie. **A.** The laryngoscope has been inserted and the bougie advanced into the hypopharynx. **B.** The bougie is advanced under the epiglottis. **C.** The bougie is inserted into the trachea and advanced over the tracheal rings. **D.** The bougie is advanced until its tip is at the carina or mainstem bronchus. **E.** The endotracheal tube is advanced over the bougie and into the trachea.

or adult patient's lips, or 24 cm in the child, it is most likely in the esophagus or stomach. One study noted the bougie getting caught and the palpation of "clicks" to be a less reliable indicators of tracheal placement than in some other studies.²⁵ A 2014 study recommends against using the hold-up sign with single-use bougies.²⁶ The same study cautions clinicians when trying to elicit this sign with reusable bougies.²⁶

An assistant performing the Sellick's maneuver should feel the tip of the bougie passing under their fingertips as it is advanced down the trachea. The bougie will rotate as the tip passes the carina and enters a mainstem bronchus. It will rotate clockwise if it enters the right mainstem bronchus and counterclockwise if it enters the left mainstem bronchus. Correct positioning can be checked by using an end-tidal CO₂ monitor or detector attached to the Rapi-Fit adaptor of the bougie.

Instruct an assistant to load the endotracheal tube over the bougie and slide it to the level of the patient's lips. **The assistant should hold and advance the endotracheal tube until its tip is at the patient's lips while the Emergency Physician controls the bougie, controls the laryngoscope, and provides instruction to the assistant. The Emergency Physician must now grasp and control the endotracheal tube with their right hand while the assistant holds the bougie securely in place.** Advance the endotracheal tube over the bougie and into the trachea (Figure 22-8E). Rotate the endotracheal tube 90° counterclockwise under direct visualization so that the bevel is facing posteriorly as the endotracheal tube passes through the vocal cords. This maneuver allows the endotracheal tube bevel to not get caught on the arytenoid cartilage and to gently spread the arytenoids with a minimum of force, thus avoiding any injury to the vocal cords.²⁷ **Do not try to advance the endotracheal tube if resistance is encountered.** Instruct the assistant to slightly withdraw the endotracheal tube, rotate it in a slightly more counterclockwise direction, and re-advance it again.

Hold the endotracheal tube firmly in place. Remove the laryngoscope. Remove the bougie. Secure the endotracheal tube, confirm its proper position, and begin ventilation of the patient.

Little training is needed before successful intubation using a bougie. This may be due to the similarity to the standard intubating technique and the familiarity with the Seldinger technique that is used during the intubation process. An observational prehospital study showed that bougies were used to successfully intubate 78% of difficult airways that could not be managed by standard techniques.²⁸

ALTERNATIVE OROTRACHEAL INTUBATION TECHNIQUE

An assistant is not always available to load the endotracheal tube and advance it over the bougie. Likewise, an airway may turn out to be difficult when it is not anticipated. An alternative is for the Emergency Physician to preload the endotracheal tube on the bougie (Figure 22-9) and insert them as a unit.²⁹⁻³¹ Load the endotracheal tube over the bougie so that the bougie projects approximately 10 cm from the distal end of the endotracheal tube (Figure 22-9A). Form a loop with the endotracheal tube and proximal bougie and grasp it with the right hand (Figure 22-9A). A second technique is to load the endotracheal tube on the bougie so that the bougie projects approximately 6 to 10 cm from the distal end of the endotracheal tube and grasp it with the right hand (Figure 22-9B).

Insert the laryngoscope into the patient's mouth and attempt to visualize the glottis. Grasp the bougie loaded with the endotracheal tube in the right hand. Insert the distal end of the bougie through the vocal cords and into the trachea. Remove the laryngoscope. Advance the endotracheal tube over the bougie and into the trachea. Securely hold the endotracheal tube. Remove the bougie. Secure the endotracheal tube, confirm its proper position, and begin ventilation of the patient.

BOUGIE-GUIDED SUPRAGLOTTIC AIRWAY INSERTION

Bougies can be used to guide supraglottic airway devices.³²⁻³⁴ A bougie was used as a guide through the ProSeal LMA.^{32,35-37} The esophageal channel of the laryngeal mask airway (LMA) was used to load the bougie and place it in the esophagus. This resulted in a better success rate than using the LMA introducer tool. The bougie-guided insertion caused less trauma than the LMA insertion tool after failed digital insertion of the ProSeal LMA. A similar technique has been used in the pediatric population.³³ Other studies have used bougies as guides through a supralaryngeal device for rescue intubation.^{34,38}

BOUGIE-ASSISTED RETROGRADE INTUBATION

Retrograde intubation with a bougie may be considered as an emergent airway management option.³⁹ A patient was successfully intubated using a modified retrograde technique through

A

B

FIGURE 22-9. Two methods to preload an endotracheal tube onto a bougie. **A.** The curved hold. **B.** The straight hold.

a tracheal defect with a bougie. The bougie is often more conveniently available than a retrograde guidewire kit. A bougie can be inserted through the skin and airway incision, laceration, or defect and advanced superiorly to exit the patient's mouth. The endotracheal tube can then be loaded over the bougie and advanced into the trachea. Refer to Chapter 30 for the complete details of retrograde intubation.

BOUGIE-ASSISTED CRICOTHYROIDOTOMY

Various medical and surgical specialties have used the bougie as an aid when performing a cricothyroidotomy.⁴⁰⁻⁴² Using a bougie as an aid was found to be easier and faster to teach how to perform a cricothyroidotomy in an animal lab than a traditional cricothyroidotomy.⁴³ The military describes this as the preferred technique of combat airway management.⁴⁴ The three-step technique using the bougie can be quickly taught to combat medics and performed in complete darkness using night vision goggles. A bougie placed through the incision maintains the open tract, provides tactile confirmation of tracheal placement, and serves as a guide for the endotracheal tube insertion.

ALTERNATIVE USES

Various other applications of the bougie have been described.⁴⁵⁻⁵⁶ The bougie can be used as an adjunct in nasal intubation in the adult and pediatric populations.^{45,46,49} The bougie has been successfully used to aid in correct placement of a double-lumen airway tube in a difficult airway.⁴⁷ It has also been described and tested as a back-up device during extubation to allow for a quick reintubation in case of the need to resecure the airway.⁴⁸ A bougie can be used as an endotracheal tube exchanger, which is performed mainly in the Operating Room or Intensive Care Unit if direct visualization of the vocal cords by a repeated direct laryngoscopy is difficult to achieve. Bougies can be used to facilitate intubation in conjunction with a video laryngoscope or a fiberoptic bronchoscope.^{50,51} It can also be used as an adjunct with blind digital intubation.⁵² A bougie can be used during chest compressions of cardiopulmonary resuscitation without stopping.^{53,54} A bougie can be used to intubate and ventilate one lung in cases of severe hemoptysis.⁵⁵ Finally, the bougie has been inserted through an endotracheal tube to confirm its proper placement.⁵⁶

COMPLICATIONS

There are some complications specific to the use of a bougie. The bougie can cause trauma to the airway soft tissues.^{14-16,57-59} The Frova causes significantly more complications than other bougies (5% incidence versus rare).⁵⁷ This difference is most likely due to using the metal cannula, making the Frova quite stiff. The Frova with the metal cannula exerts more force on the airway tissues than other bougies.^{19,58} Using the Frova without the metal cannula will reduce the incidence of tissue trauma. Single-use bougies may be more prone to cause soft tissue trauma when compared to multiple-use bougies, especially if they are held close to the distal end.^{17,58} A false passage can be created by the tip of the bougie penetrating the soft tissues.¹⁴ Insertion of an endotracheal tube over the bougie and into a false passage can increase the amount of soft tissue damage and hemorrhage. Insufflation of air into the surrounding soft tissues can compress the trachea and cause an external airway obstruction. A bougie can perforate the airway and result in a tension pneumothorax.⁶⁰ Advancement of the bougie into the trachea or a mainstem bronchus can induce bronchospasm.⁵⁷ The remainder of the complications are similar to those of orotracheal intubation (Chapter 18).

SUMMARY

Bougies are widely used to aid in intubation with traditional direct laryngoscopy when the glottic opening cannot be adequately visualized. They have been successfully used both in the adult and pediatric populations, with devices available for use with endotracheal tubes as small as 3.0 mm in size. They are also used to aid in placement of supralaryngeal devices, blind nasotracheal intubations, placement of double-lumen airway tubes, retrograde intubation, cricothyroidotomies, video laryngoscopy, and fiberoptic bronchoscopes. A bougie should be a required device in any emergency or difficult airway cart.

Digital (Tactile) Orotracheal Intubation

James A. Heilman, Beech Burns, and O. John Ma

INTRODUCTION

Digital orotracheal intubation is an alternative advanced airway technique that has been demonstrated to be effective when performed by trained prehospital, aeromedical, combat, and hospital providers.¹⁻¹⁸ The index and middle fingers are used to direct the endotracheal tube into the patient's larynx. This technique is "blind" in that the airway is not visualized at any point during the procedure. Use this technique in the Emergency Department as a secondary or tertiary method. It may be particularly useful when oral secretions or blood inhibit direct visualization of the upper airway.¹ There is evidence in hospitalized neonatal patients that digital intubation may be more effective than direct laryngoscopy as a primary method of orotracheal intubation.^{2-4,14}

ANATOMY AND PATHOPHYSIOLOGY

The significant anatomic structures that the Emergency Physician will encounter are the patient's tongue and epiglottis. The epiglottis is the cartilaginous structure that is located at the root of the tongue and serves as a valve over the superior aperture of the larynx during the act of swallowing.⁶ Refer to Chapters 9 and 18 for a more complete discussion of the airway anatomy.

INDICATIONS

Digital orotracheal intubation is an alternative technique for intubating the comatose or chemically paralyzed patient. There are three major indications for digital intubation. The equipment required to perform direct or video laryngoscopy is either not available or not functioning. The physical positioning of the patient does not permit the provider to intubate using direct or video laryngoscopy.⁷ Visualization cannot be achieved using conventional techniques due to trauma, excessive secretions, or blood in the airway.¹

This technique involves minimal movement of the head and neck. It may be a suitable method for intubating patients with known or suspected cervical spine injuries. Digital intubation may be a useful procedure for paramedics and aeromedical personnel in the out-of-hospital setting, when trapped patients require intubation but are not in a position for more conventional methods.⁷ It is an alternative technique for out-of-hospital intubation where other techniques and equipment are unavailable or limited.

This procedure may be considered a primary method of intubation in neonatal patients.^{2,4,5} One small study demonstrated that digital intubation of the neonate was more successful and faster than direct laryngoscopy when performed by a very experienced neonatal intubator.³ The first-pass success rate was 90.5% for the digital

intubation versus 50% for the direct laryngoscopy, with a mean time to intubation of 8.2 seconds and 13.1 seconds, respectively.

Digital intubation may be a life-saving technique for difficult airways.^{16,17} Adequate skill training and maintenance of competency are critical to achieve successful outcomes. Medical flight crewmembers and Emergency Medicine residents in a simulated tactical setting were found to require more attempts and take longer to provide advanced airway management with digital intubation compared to direct laryngoscopy and King LT tube placement.¹³ Digital intubation only had a 14% success rate in a large prospective prehospital difficult airway study.¹⁴ Adequate training for digital intubation is paramount, and the Emergency Physician should choose airway techniques with which they are most familiar before considering secondary or tertiary methods in a patient with a difficult airway.

CONTRAINDICATIONS

There are no absolute contraindications to digital intubation. The main danger of this procedure is to the Emergency Physician who is at risk for having their fingers bitten by the patient. **Do not perform this technique on any patient who is awake or semiconscious.** It should be performed only on patients who are paralyzed or unconscious. Relative contraindications would be performing this procedure on a patient with multiple fractured teeth that may abrade or cut the fingers or a patient whose ingestion may present a biochemical hazard.

EQUIPMENT

- Endotracheal tubes, various sizes
- 10 mL syringe
- Water-soluble lubricant or anesthetic jelly
- Bag-valve device
- Oxygen source and tubing
- Gloves
- Gauze 4×4 squares
- Wire malleable stylet (optional)
- Bite block (optional)
- Bougie (optional)
- Supplies for orotracheal intubation (Chapter 18)

PATIENT PREPARATION

Digital intubation in the Emergency Department is commonly performed on an emergent or urgent basis. Explain the risks, benefits, and complications of the procedure to the patient and/or the patient's representative if there is time.

The use of gloves, a bite block, and gauze over the teeth as guards is recommended when performing this procedure. Place the patient supine. Immobilize the cervical spine if the patient has sustained a concerning mechanism of injury. An assistant can help hold the patient's head to maintain in-line immobilization. Place the patient on continuous cardiac monitoring, pulse oximetry, and supplemental oxygen. The remainder of the preparation is the same as for orotracheal intubation (Chapter 18).

Prepare the endotracheal tube. Attach a 10 mL syringe to the cuff's inflation port. Inflate the cuff and inspect it for any air leaks. Deflate the cuff and leave the syringe attached to the inflation port. The use of a stylet is optional, but one is commonly used by most practitioners in this procedure.¹⁰ A stylet may be used if the patient's larynx is anterior, the intubator has short fingers, or it is the Emergency Physician's preference. Lubricate and insert the stylet until it is 1 cm proximal to the distal end of the endotracheal tube. Bend the malleable stylet just as it enters the endotracheal tube. This will

FIGURE 23-1. The index and middle fingers are placed in the right side of the patient's mouth and advanced until the epiglottis is palpated. The endotracheal tube is inserted into the patient's mouth between the two fingers.

prevent it from migrating distally and injuring the patient. Gently bend the distal end of the endotracheal tube into a "J".¹ Liberally lubricate the distal end of the endotracheal tube. Induce anesthesia if the patient is conscious.

TECHNIQUE

Stand at the patient's right side, facing the patient. Open the patient's mouth. Insert the index and middle fingers of the right or dominant hand into the right angle of the patient's mouth (**Figure 23-1**).^{1,3} Slide the fingers along the surface of the tongue until the epiglottis is palpated. The metacarpophalangeal joints of the index and middle fingers will usually be at the level of the patient's incisors in an adult. The tip of the epiglottis is approximately 8 to 10 cm from the incisors. Elevate the epiglottis with the index finger (**Figure 23-2**). An assistant or the thumb of the nondominant hand may be used to provide cricoid pressure if needed.¹¹

Insert the endotracheal tube with the left or nondominant hand along the left side of the patient's mouth and between the two fingers

FIGURE 23-2. Advancing the endotracheal tube. The epiglottis is elevated with the index finger. The endotracheal tube is advanced between the fingers and into the larynx.

(Figures 23-1 and 23-2).^{1,3} Alternatively, the endotracheal tube can be advanced between the two fingers and the tongue. Gently advance the tip of the endotracheal tube into the patient's trachea (Figure 23-2).

Do not advance the endotracheal tube if any resistance is encountered. Partially withdraw the endotracheal tube and attempt to reinsert it into the patient's trachea. An alternative is to withdraw the endotracheal tube completely, bend it more acutely, and attempt reinsertion.

Have an assistant withdraw the stylet if one was used. Advance the endotracheal tube approximately 3 to 4 cm.^{1,12} Securely hold the endotracheal tube with the left or nondominant hand and carefully withdraw the other hand from the patient's mouth. Inflate the cuff of the endotracheal tube. Begin ventilating the patient while securely holding the endotracheal tube and confirming proper placement (Chapter 19).

The technique of digital orotracheal intubation may require some modification under certain circumstances. **A patient's mouth may appear too small to allow an endotracheal tube and two fingers.** Use the fingers in the patient's mouth to push their jaw and tongue forward. If the patient's mouth still appears too small, apply gauze squares over their mandibular incisors and push their mouth open further using the bases of the fingers in the patient's mouth.

It may be difficult to blindly identify the patient's epiglottis. Insert the fingers in the midline of the patient's mouth and slowly push them posteriorly. The fingers will roll off the posterior portion of the tongue and allow palpation of the epiglottis. **Do not push the epiglottis posteriorly.** Once identified, move fingers to the right side of the patient's mouth while the fingertips are in constant contact with the epiglottis.

Some may be concerned their fingers are not long enough to palpate the epiglottis. Push the soft tissue in the right angle of the patient's mouth posteriorly while inserting the fingers posteriorly in their mouth. This will allow the fingers to reach more posteriorly. This may not work in tall thin patients. Try a supraglottic device (Chapter 25) or bougie (Chapter 22) if using the fingers does not work.

This technique can be used in patients of all ages, including neonates, with only minor variations in technique.³⁻⁵ Use only the index finger for neonates and young children when performing this procedure.³ Use the appropriate-size suction catheter or endotracheal tube as would be used to orally intubate the child. **Do not insert the catheter or endotracheal tube using this technique if the child is spontaneously breathing because their vocal cords may be damaged.**

An alternative approach involves introduction of a bougie into the trachea using the technique described above followed by the passage of an endotracheal tube over the bougie (Figure 23-3).^{13,17,18}

A

B

C

D

FIGURE 23-3. The bougie-aided digital intubation. **A.** The fingers have been inserted into the mouth to elevate the tongue and epiglottis. **B.** The bougie is advanced into the trachea. **C.** The endotracheal tube is inserted over the bougie. **D.** The bougie has been removed and the endotracheal tube remains. (Used with permission from reference 18.)

Advantages of this approach include the smaller diameter and malleability of the bougie; tracheal clicking with the bougie, which can help confirm proper placement; and the ability to easily carry a bougie into tactical environments.

ASSESSMENT

The placement of an endotracheal tube should be followed by an assessment to ensure its proper positioning (Chapter 19). This includes visual inspection of chest rise with ventilation, lack of abdominal movement with ventilation, fogging in the endotracheal tube for at least six breaths, auscultation, and end-tidal CO₂ monitoring. This should be followed by a chest radiograph to confirm proper positioning of the endotracheal tube within the trachea.

AFTERCARE

The steps of ensuring proper placement of the endotracheal tube and securing the tube are the same as for any patient who has undergone orotracheal intubation (Chapter 18).

COMPLICATIONS

No significant complications to the patient have been identified with digital intubation. One study involving a small number of cadavers found that digital intubation predisposes to left mainstem bronchial intubation.⁹ The investigators concluded that decreased right-sided breath sounds after tactile intubation may represent an easily corrected left mainstem intubation rather than more concerning pathology. An awake or semiconscious patient may gag with subsequent vomiting, aspirate, and injure the Emergency Physician's fingers. Insert a bite block for added safety between the patient's molars if its placement still allows enough space in the patient's mouth for two fingers and the endotracheal tube. The possibility of esophageal intubation is significant, especially if the intubator has small fingers or the airway is anterior. Hypoxemia can result from numerous attempts at intubation without any intervening ventilations. Insert the endotracheal tube gently to prevent traumatic injury to the patient's hypopharynx, vocal cords, or trachea.¹⁰

SUMMARY

Digital (tactile) intubation is a viable alternative technique for the management of the difficult airway. Prehospital, aeromedical, combat, and Emergency Physician providers should receive training in this technique. It is an expedient method for intubating a comatose or chemically paralyzed patient if the upper airway cannot be visualized because of trauma, secretions, or blood. This technique may be the only method available in certain environments due to patient positioning and lack of advanced airway equipment.

Lighted Stylet Intubation

Jaroslav Tymouch, Gennadiy Voronov, and Ned F. Nasr

INTRODUCTION

Direct laryngoscopy is the most common method of tracheal intubation in the Emergency Department. Tracheal intubation in critically ill patients is a high-risk procedure. The risk of complications increases with repeated or prolonged attempts. **Make expedient first attempt success the goal for airway management in these patients.** Patient-related factors often make visualization of the airway and placement of the tracheal tube difficult. Physiologic derangements reduce the patient's tolerance for repeated or prolonged attempts at laryngoscopy. This results in hypoxemia and hemodynamic deterioration. Operator-related factors (e.g., experience, device selection, and pharmacologic choices) affect the odds of a successful intubation on the first attempt. Direct laryngoscopy will be difficult or impossible in approximately 1% to 3% of patients requiring intubation.¹⁻⁴ This may be due to many different causes (e.g., excessive airway bleeding, limited cervical spine mobility, or limited cervical spine mobility). Blind intubation using a lighted stylet in these situations is a proven valuable technique.⁵⁻¹⁴

Light-guided intubation relies on the transillumination of the soft tissue of the neck to indicate intratracheal endotracheal (ET) tube placement. A bright and well-defined glow is seen in the anterior neck when the light is in the trachea (**Figures 24-1 and 24-2A**). A diffuse and less intense glow is seen with esophageal intubation (**Figure 24-2B**). Lighted stylet intubation is a relatively easy technique to learn and rapid to perform.

The concept of using a light-guided introducer for orotracheal intubations first appeared in print in the late 1950s.^{1,2,5,6} Several authors described ingenious devices to tunnel a light bulb attached to an introducer through the ET tube and power it with a pocket battery, penlight, or laryngoscope handle.^{1,2,5,6} These primitive devices were simple and effective. Further development of this technology was stagnant until the late 1970s when several authors described use of the Flexillum surgical light as a lighted stylet or "light wand."^{7,8} The makers of the Flexillum light revised the design after a few problems

FIGURE 24-1. A bright and well-circumscribed glow (arrow) is seen below the thyroid prominence when the lighted stylet enters the glottis. (Used with permission from Hung O, Murphy MF (eds): *Management of the Difficult and Failed Airway*, 2nd ed. New York: McGraw-Hill; 2012.)

with bulb dislodgment and marketed the first lighted stylet known as the Tube-Stat.^{9,15} A similar design is still available as the Tube-Stat lighted intubating stylet (Medtronic Xomed, Jacksonville, FL). Laerdal introduced the more sophisticated Trachlight in the mid-1990s (Figure 24-3). It was an improvement over previous lighted stylets with a more intense light source, a more flexible light wand, and a separate retractable stylet that adjusts to a variety of ET tube lengths.¹⁰ There are numerous lighted stylets today (Figures 24-3 through 24-6 and Table 24-1).

ANATOMY AND PATHOPHYSIOLOGY

The trachea lies anterior in the neck and is covered only by the skin, subcutaneous tissue, and pretracheal fascia. The esophagus lies posterior to the trachea surrounded by much more soft tissue (Chapter 9). A light source positioned within the trachea will transilluminate a bright and discrete glow that can easily be

FIGURE 24-2. Use of a lighted stylet. **A.** The tip of the ET tube is in the glottic opening and below the thyroid prominence at the glottic opening. **B.** The tip of the ET tube is in the esophagus. Vital Signs Light Wand	GE Healthcare	Adult sizes Bulb keeps below 42°C or 108°F Malleable stylet Reusable

seen on the surface of the neck (Figures 24-1 and 24-2A). A light source directed within the esophagus will be diffused by the surrounding tissue and appear dull (Figure 24-2B). The Emergency Physician can easily discriminate between the dull, diffuse transillumination of an esophageal light source and the more discrete, intense signal transmitted from within the trachea. A submental, superior to the hyoid bone, glowing light indicates that the tip is positioned in the vallecula. A lateral glowing light indicates placement in the pyriform sinus.

Lighted stylet tracheal intubation requires practice and is easily learned. Intubation training influenced the speed of intubation but not the success rate on the first attempt.¹⁶ The average time for a successful intubation was 42 seconds in the first 25 attempts. This time decreased to an average of 32 seconds for the second 25 attempts. All lighted stylet intubations were successful by the third attempt. Videographic study of 125 children tracheally intubated by anesthesia residents with little or no lighted stylet experience had an overall success rate of 83%.¹⁶ Failures were due to a too large tracheal tube or persistent entry into the vallecula or esophagus.

Traditional methods of estimating the degree of difficulty in achieving tracheal intubation under direct laryngoscopy may not apply when a lighted stylet approach is undertaken. In two studies, 200 patients who were predicted to be easy intubations with direct laryngoscopy were intubated with a lighted stylet.^{17,18} Approximately 87% were intubated on the first attempt with a lighted stylet and 99% within three attempts. There was no correlation between the time to intubate and any of the airway prediction variables in the Trachlight group in a series of 950 patients.¹⁰ This contrasted with the direct laryngoscopy group, in which some of the airway variables (e.g., the Mallampati score and the circumference of the neck) did correlate with the time to intubate the trachea.

Laryngoscopy and ET intubation are intensely stimulating procedures. Both are associated with varying degrees of sympathetic activity, which may be detrimental in patients with coexisting conditions. Several investigations of the possibility that lighted stylet intubation may result in less stimulation than direct laryngoscopy and may offer some protective effects from sympathetic hyperactivity did not confirm this to be true. There is some tendency for lower blood pressure and heart rate in a lighted wand group. A study that compared two direct laryngoscope blades (i.e., the Macintosh 3 and the Miller 2) with lighted stylet intubation showed no significant difference in hemodynamic changes among the three groups.¹⁹

The difficult airway is one of the most common indications for the use of the lighted stylet. This is especially true in situations with acute oropharynx-tracheal angles, increased secretions, or bleeding causing failure of intubation with direct or fiberoptic laryngoscopy. It can be used as a back-up technique or primarily if direct laryngoscopy is predicted to be difficult. There are limited data comparing lighted stylet intubations to other rescue techniques.^{17,20-24} Lighted stylet intubations are faster and have fewer complications than blind nasal tracheal and bronchoscopy-assisted intubations.^{13,17,24} Lighted stylets are easier to use, less expensive, and more portable than fiberoptic bronchoscopes.^{17,22} Experience must be gained from intubating normal airways before it can be relied on for the difficult case.

INDICATIONS

There are numerous indications for lighted stylet intubation (Table 24-2). Lighted stylet intubation is a valuable rescue technique in patients who can be ventilated and oxygenated but are unable to be intubated with direct laryngoscopy. It is particularly useful in patients who have cervical spine immobilization, extensive blood in the hypopharynx, extensive oral trauma, extensive secretions in the hypopharynx, limited jaw opening, limited neck movement, or loose teeth that limit visibility.^{16,20-22,25-27} Lighted stylet intubations can be performed as part of rapid sequence intubation. They can be used on spontaneously breathing patients who are sedated and have topical airway anesthesia. Lighted stylets can be used for oral or nasal intubations.^{25,28} This technique can also be used for pediatric patients and infants.^{16,22,25-27}

There are some cases of emergency tracheal intubation using a modified lighted stylet technique in patients with clenched jaws in whom nasal intubation was contraindicated.²⁹ The lighted stylet was inserted behind the third molars as the cheek was retracted. The tip of the ET tube was then advanced toward the larynx in a paramedian approach and was guided by the typical transillumination. A lighted stylet can be used for intubation of patients with cervical spine injuries.²⁶ This allows the administration of cricoid pressure while keeping the cervical spine in a neutral position. There is no influence from blood and secretions in the airway.

CONTRAINDICATIONS

Intubation with lighted stylets is relatively safe and simple. There are few contraindications to this technique. **Patients with laryngeal trauma should have direct laryngeal visualization for intubation rather than a blind technique that may cause additional trauma.** Do not use a lighted stylet if there is any active infection or known tumor of the posterior pharynx or upper airway. The presence of an airway foreign body, epiglottitis, a laryngeal polyp or tumor, a

Cervical arthritis	
Known or suspected cervical spine injury	

retropharyngeal abscess, or tracheal stenosis precludes the use of this technology. It may be less successful in bright sunlight, obese patients, and patients with very dark skin.^{18,20,21}

Lighted stylets are relatively contraindicated in patients who cannot be oxygenated and ventilated. It can be used in this situation by very experienced Emergency Physicians while simultaneous preparations are under way for a cricothyroidotomy (Chapter 32). Lighted stylets should be used only by Emergency Physicians who have sufficient experience and training with the equipment and the technique.

Sometimes the lighted stylet meets resistance when it is advanced. It should be withdrawn, redirected, and advanced only if it passes with ease. **Abandon the technique and use an alternative method to intubate the patient if unexpected difficulty occurs during its passage.**

EQUIPMENT

- Lighted stylet
- ET tubes, various sizes
- 10 mL syringe
- Water-soluble lubricant
- Bag-valve device
- Equipment for orotracheal intubation (Chapter 18)

The basic unit of a lighted stylet is quite simple. It consists of a handle, a malleable stylet, and a light on the end of the stylet (**Figure 24-7**). Numerous variations exist on the basic unit. The handle contains the battery, on-off switch, and sometimes an on-off indicator light. The stylets may be reusable or single-use disposable devices. The stylet is malleable and available in numerous sizes. Longer stylets allow for nasal and oral intubation in adults. Stylets are also available in smaller lengths and widths to allow for use in small ET tubes for infants and children. The stylet is inserted into the ET tube instead of a standard stylet.

Numerous devices are available (**Table 24-2**). Examples include the Trachlight (**Figure 24-3**), the Light Wand (**Figure 24-4**), the Surch-Lite (**Figure 24-5**), and the Tube-Stat (**Figure 24-6**). There are slight differences in design. They all rely on using a lighted stylet inside the ET tube to transilluminate the anterior neck and guide blind intubation of the trachea. The Tube-Stat (Medtronic Xomed, Jacksonville, FL) is an example of the simplest lighted stylet (**Figure 24-6**). It incorporates a stylet, power source, and light bulb all in a single piece. The unit is inserted into the ET tube in place of the stylet. A switch on the handle activates the light. The Trachlight (Laerdal Medical Corporation, Wappingers Falls, NY) consists of a battery-powered handle, the light wand, and a separate stylet that inserts into the light wand (**Figures 24-3 and 24-7**). It is a simple device to operate. It is likely that further developments will continue to make these and similar models attractive options in airway management.

FIGURE 24-7. The Trachlight lighted stylet.

PATIENT PREPARATION

Prepare the patient as for any other intubation (Chapter 18). Obtain intravenous access and hemodynamic monitoring (e.g., an automatic blood pressure monitor, cardiac monitor, and continuous pulse oximetry). Prepare suction and have it immediately available. Rapid sequence intubation (Chapter 16) with an induction agent and paralytic agent is the most common technique used in the Emergency Department. Lighted stylet intubations can be performed with mild sedation and topical anesthesia in cooperative patients.

Preoxygenate the patient prior to airway manipulation. The position of the neck can be neutral, unlike with other techniques. The “sniffing” position is not required for this technique. The anterior half of a cervical collar must be opened or the entire collar removed to be able to visualize the glowing light. An assistant can maintain in-line stabilization of the cervical spine when the collar is opened or removed.

TECHNIQUE

OROTRACHEAL INTUBATION

The exact technique will depend on the type of lighted stylet or light wand used. This technology varies by manufacturer. Be familiar with the equipment and manufacturer’s instructions prior to adopting lighted stylets for use clinically. This text describes the general guidelines for the lighted stylets available. The reader is urged to take advantage of the teaching videos supplied by some manufacturers.

Check that the light source is working and apply a water-based lubricant to the stylet. Attach a 10 mL syringe to the ET tube cuff inflation port and ensure the integrity of the cuff. Insert the lighted stylet through the ET tube. **Ensure that the tip of the lighted stylet is just inside the ET tube so that the lighted stylet does not damage soft tissues.**

Bend the tip of the ET tube and lighted stylet just proximal to the cuff or about 3 to 6 cm from the distal end (**Figure 24-8**). The bend may have to be a little more proximal or distal depending on the length of the patient’s neck. Measure the mandibular-hyoid distance in the patient. Place the index finger in the submental space below the chin and determine the number of finger breadths between the mandible and the hyoid bone.¹² Typical measurements are 1 to 3 finger breadths. Bend the tip of the ET tube and lighted stylet sharply at a site that approximates the mandibular-hyoid distance between the bend and the junction of the lighted tip of the stylet. This is usually 3 to 6 cm from the distal end of the ET tube and just above the cuff. Avoid making the bend at the cuff, if possible, to prevent damaging the cuff. **Be sure the bend is about 90° to allow the maximal light intensity to be directed anteriorly.**

Stand above or to the side of the patient’s head. The lighted stylet, unlike the traditional laryngoscope, can be held in either hand. Lower the bed to facilitate insertion of the lighted stylet. Grasp the patient’s jaw with the nondominant hand. Place the nondominant thumb on the mandibular molars and the nondominant fingers under the body of the mandible. Lift upward and inferiorly to open the jaw, elevate the tongue, and elevate the epiglottis. Grasp the lighted stylet with the dominant hand and turn it on. It is best held with a “pencil grip” over the proximal ET tube.

Introduce the ET tube from the side of the patient’s mouth and bring it to the midline. The handle will project toward the patient’s feet as the hockey stick-shaped tip is placed over the tongue (**Figure 18-8A**). Advance the tip by moving the handle in a vertical arc toward the patient’s head (**Figure 18-8B**). This will bring the ET tube tip toward the vocal cords. A bright light will be seen

FIGURE 24-8. Insertion of the lighted stylet. **A.** Insert the hockey stick–shaped ET tube containing the lighted stylet over the tongue. **B.** Move the ET tube in a vertical arc toward the patient's head. The bright light transilluminates the anterior neck as the lighted stylet approaches the trachea. **C.** The ET tube is advanced into the trachea.

in the midline of the neck just below the hyoid bone (**Figures 24-1 and 24-9A**). **The tip of the ET tube is in the vallecula if the light is in the submental space (Figure 24-9B).** **The tip of the ET tube is lodged in the pyriform sinus if the light is lateral (Figure 24-9C).** **A dull, faint light in the midline signifies that the tip of the ET tube is in the esophagus (Figures 24-2 and 24-9D).** Simply withdraw the malpositioned ET tube, reposition it in the midline, and advance it again.

It is safe to advance the ET tube once a bright and discrete light is detected in the midline at the level of the thyroid cartilage (i.e., Adam's apple). **Advance the ET tube while observing the transilluminating light march down the neck to the suprasternal notch (Figure 24-9A).** The light will disappear as the tube passes behind the suprasternal notch. The epiglottis is obstructing its advancement if the glowing light is in the midline and the ET tube is resistant to

advancement. Slightly rock the unit in the sagittal plane (i.e., from the patient's head to their feet) to slip the tip of the ET tube under the epiglottis. Remove the lighted stylet if resistance is still encountered. Ventilate the patient with a bag-valve-mask device. Load a smaller ET tube onto the lighted stylet and try again. The tip of the ET tube is appropriately positioned midway between the vocal cords and carina at the point the light is lost.³⁰ Remove the lighted stylet, inflate the ET tube cuff, confirm proper ET tube placement, secure the ET tube at the lips, and begin ventilating the patient.

Use caution in very thin or very obese patients. A bright light may be visible when the stylet is in the esophagus in the thin patient. Gently rock the light off midline to compare the diffuse dull light to that seen when the light is truly midline. The extra soft tissue in the obese patient may dull the light. Dim the room lights to facilitate adequate visualization.

FIGURE 24-9. Appearance of the transilluminated light of the lighted stylet based on the location of the tip. **A.** Proper placement in the larynx with a bright distinct light in the midline at the level of the thyroid cartilage. The light moves down the anterior neck and disappears behind the sternal notch (*dashed arrow*) with advancement of the ET tube. **B.** Incorrect placement in the vallecula causes a submental glow superior to the hyoid. **C.** Incorrect placement in the pyriform sinus causes a glow off the midline. **D.** Incorrect esophageal placement causes a diffuse, dull, or absent light.

FIGURE 24-10. Nasotracheal intubation using a lighted stylet. A bright and well-circumscribed glow (arrow) is seen below the thyroid prominence when the lighted stylet enters the glottis. (Used with permission from Hung O, Murphy MF (eds): *Management of the Difficult and Failed Airway*, 2nd ed. New York: McGraw-Hill; 2012.)

The glowing light must maintain a continual brightness to demonstrate tracheal intubation. The ET tube has been misplaced in the esophagus if the glowing light is briefly lost or dulls and then returns (Figure 24-2). The brief loss or dulling of the glowing light corresponds to its passage behind the larynx. The return of the bright glowing light corresponds to the ET tube advancing past the larynx and into the esophagus. This is commonly seen in infants, small children, and very thin adults. Gently withdraw the lighted stylet while applying anteriorly directed traction to the tip of the stylet. Stop withdrawing the lighted stylet when the glowing light suddenly intensifies after it exits the esophagus. Readvance the lighted stylet, as previously described, while applying anterior traction on the unit to help it enter the larynx.

NASOTRACHEAL INTUBATION

The procedure for nasotracheal intubation is similar to orotracheal intubation with the lighted stylet with a few differences (Figure 24-10). Treat the nasal passages with a topical anesthetic and a topical decongestant to vasoconstrict the mucosal tissue (Chapter 29). The nasal passage may need to be dilated to accommodate the ET tube. The lighted stylet should have a gentle curve of about 100° to 120°. The bend-to-tip length should correspond to the distance from the posterior nasopharynx to the cricothyroid membrane.

ASSESSMENT

Assess the patient continuously at every step of the procedure to assure adequate oxygenation and ventilation. Confirm the position of the ET tube by end-tidal CO₂ monitoring, esophageal detector device, fogging in the ET tube for at least six ventilations, auscultation, and chest radiograph (Chapter 19). Secure the ET tube.

AFTERCARE

The ongoing care of the patient should proceed as with any other intubation technique. Routine care of the ET tube is no different. The manufacturer's guidelines should be followed for maintenance of the equipment.

COMPLICATIONS

Intubation with a lighted stylet is a very safe procedure with a very low complication rate.^{13,21} There are only a small number of reported complications in over 30 years of use. These include two reports of accidental bulb dislodgment, two arytenoid dislocations, one case of stylet fracture, a lacerated frenulum, and varied reports of mild soft tissue trauma.^{9,10,15,31-33} Dysphagia, hoarseness, and a sore throat occur less frequently with lighted stylets than with direct laryngoscopy.¹⁴ The cases of equipment failure have been in older models of lighted stylets. There are data to suggest that lighted stylet intubations are less traumatic than direct laryngoscopy.¹⁴ No complications were noted in 253 patients intubated with lighted stylets.²¹ Intubation with lighted stylets may cause less cervical spine motion compared with direct laryngoscopy.³⁰

The newer models have been revised to minimize problems and have been remarkably free of adverse events. Complications with this technique are unusual in experienced hands. Weis and Hatton reported no complications in 253 patients intubated with a lighted stylet.²¹ Success rates with lighted stylet intubation are comparable to those with other techniques. Success rates on first attempts are reported to be as low as 70% with the Tube-Stat and as high as 92% with the Trachlight.^{10,11,13,14,17,27,34} Success rates approach 100% when multiple attempts are allowed.^{12,17} Success rates of 88% have been reported in the prehospital setting under adverse and emergent conditions.¹⁸ The rates of successful intubation remain high for difficult airways. Hung and colleagues reported the successful intubation in 95 of 96 known difficult airways.²⁰ This included patients with prior difficult or failed intubations by direct laryngoscopy, patients with unstable cervical spines, patients with ankylosing temporomandibular joints, and the morbidly obese. Holzman and colleagues reported successful intubation in 30 of 31 children with anatomic airway abnormalities.²²

Intubation times with lighted stylets are comparable to those with other techniques and range from 15.7 to 45 seconds.^{10-12,17,18,20-22,35} Recent evidence suggests that intubation with a lighted stylet may cause fewer hemodynamic alterations when compared to direct laryngoscopy.^{36,37} The skill level of the intubator is an important factor in success rates, time to intubation, and possibly complications.²² The best success rates are reported by those who have devoted a great deal of time to the technique and use it regularly. There is a definite learning curve, and time to intubation improves with experience.^{18,23,26} Skills may improve with practice in a cadaver lab.^{12,23} Manikins designed as intubation teaching models can be modified for use with lighted stylets.³⁴ Proper training, use of teaching videos, didactics, formal practice with training manikins and in cadaver labs, and supervised clinical experience are all important means of developing and maintaining skills and decreasing complication rates.

SUMMARY

Lighted stylet intubation is an easily learned technique that is a valuable adjunct for securing difficult airways. It is particularly useful in patients with limited jaw opening, limited neck movement, and marked airway bleeding. The American Society of Anesthesiologists includes use of lighted stylets in its recommendations for the management of difficult airways.¹¹ The American Heart Association encourages instruction in alternative airway approaches, including lighted stylets, for difficult airways.³⁸ The use of lighted stylets has proven to be rapid, safe, and effective in emergent and difficult settings.

The success of lighted stylet techniques is determined by the experience of the Emergency Physician. This technique is likely to be of greatest benefit in the occasional unexpected airway emergency.

Maintaining sufficient skills to use it in the emergent setting is a challenge. Emergency Physicians will need to devote time and effort to developing and maintaining the skills they will need to cope with an airway emergency when it presents.

Supraglottic Airway Devices

Fred A. Severyn

INTRODUCTION

Airway management and the subsequent provision of oxygenation and ventilation remains one of the foundational principles in the clinical practice of Emergency Medicine in the Emergency Department and the prehospital environment. The majority of advanced airway interventions in the prehospital environment occur in the cardiac arrest or major trauma patient with significant altered mentation. A growing body of evidence questions actual survival benefit for the practice of endotracheal (ET) intubation. A baseline proficiency in airway management via intubation requires on the order of 50 to 100 intubations, a clinical experience not commonly found in the prehospital training environment.¹ Even more disheartening are numerous studies demonstrating a significant percentage of cases of unrecognized esophageal airway placement or ET tube migration out of the airway upon Emergency Department arrival. Such therapeutic misadventures guarantee bad outcomes.² Most of these studies describe relatively busy prehospital systems with clearly defined medical oversight.

Evidence-based cardiopulmonary resuscitation (CPR) science has shown that limiting "no-flow time" associated with compression-ventilation cycles is directly related to the efficiency of resuscitation as measured by coronary perfusion pressure. Most supraglottic airway devices (SADs) can be placed with a very high first-pass success rate in under 20 seconds. This allows for progression to continuous uninterrupted compression cycles with interposed ventilations. Multiple prehospital systems have placed SADs into their protocols for the use of alternative airway devices in preference over ET intubation.^{3,4}

The spectrum of airway management begins with the Basic Life Support (BLS) skill set using airway positioning, suctioning, and ventilation support with the use of a bag-valve-mask device. The next decision is to progress to the Advanced Life Support (ALS) skill set for definitive long-term airway management via cuffed ET tube placement or a surgical airway. ALS management has revolved

around the concept of placing a cuffed ET tube. The concept of the “rescue airway device” has risen as a back-up technique after unsuccessful ET tube placement using a SAD as a conduit for oxygenation and ventilation to “buy some time.” This life-saving practice is included in difficult airway and CPR algorithms aimed at maximizing uninterrupted chest compressions.⁵⁻¹¹ **It is a reasonable expectation that the Emergency Physician develop a baseline expertise and experience with a variety of SADs.** This is for receiving patients who have had them placed and when ALS procedures do not go exactly as planned in the Emergency Department.

The original creation of SADs as airway adjuncts occurred with an initial aim at the operative airway management of patients in the Operating Room. Simplistically, SADs function as a conduit between the mouth and laryngeal inlet at the vocal cords, bypassing tongue-induced airway obstruction in the sedated and paralyzed patient during an operation.¹² The classic laryngeal mask airway (cLMA) is the original example of a SAD. It was created in 1981 and is used daily in Operating Rooms across the world with several hundred million cumulative cases of patient care experience.^{12,13}

Most Emergency Medicine residents will get a baseline exposure to the use of SADs from operative exposure.¹³ The logical migration from the Operating Room to the Emergency Department has occurred as we train the current generation. The device migration from the Emergency Department to the prehospital arena has begun. An explosion of new devices in a very competitive marketplace could easily overwhelm the Emergency Physician as to the nuances of devices and brands. Each SAD comes with manufacturing claims as to their device superiority over the competition in a very competitive marketplace. It is difficult for Emergency Physicians to keep up with the industry explosion of these airway adjuncts. The disadvantage of SADs is that they are only temporary airway devices and must be removed or replaced with another airway device within a few hours. This chapter aims to describe this group of airway adjuncts in broad basic terms, with LMA devices (Chapter 26) and dual-lumen supraglottic ventilation devices (Chapter 27) described in later chapters.

ANATOMY AND PATHOPHYSIOLOGY

ET intubation relies on the placement of a ventilation tube between the vocal cords and inferiorly into the trachea to provide a low-resistance bridge between the trachea and resuscitation/ventilation circuit. This bypasses the most commonly encountered anatomic airway obstruction, the posteriorly directed lax tongue in the supine patient. **SADs offer low resistance to gas flow, provide a variable degree of protection to the trachea from gastric and oropharyngeal secretions, and are suitable to provide positive-pressure ventilation in the apneic patient while limiting potential adverse events.**¹³ SADs are not designed to pass through the vocal cords. They rely on the close anatomic relationships between the laryngeal inlet and the upper esophagus for proper device placement and facilitation of gas movement. Some SADs allow for blind ET tube placement through the device lumen with varying degrees of success. Others are too narrow to allow ET tube placement but allow for fiberoptic visualization of vocal cord structures and direct placement of an Aintree introducer.¹⁴ The Aintree introducer can then be used as a stylet for subsequent ET tube placement following SAD removal.¹⁴

The close anatomic relationships between laryngeal inlet and esophageal orifice help explain some observed complications with SADs. The tip of the SAD was designed to go posterior to the glottis opening at the root of the esophagus. The SAD may impinge into the laryngeal orifice and obstruct airflow to some degree. The device may still “buy some time” but will not function as a definitive airway. The epiglottis may become folded over upon SAD insertion,

or it may fold into the aperture meant to sit just outside the vocal cords. This results in varying degrees of airflow obstruction and requires the removal of the SAD.

INDICATIONS

The use of SADs is reserved for the unconscious patient without an intact gag reflex, much like the use of the oropharyngeal airway.¹⁵ Use SADs in the unconscious patient who is difficult to ventilate with a face mask while preparations are being made for ET intubation. Consider a SAD in the “can’t ventilate, can’t intubate” patient when time is of the essence. The patient’s mouth must be able to open at least 1.5 to 2 cm to allow for the insertion of the SAD. SADs can be used as a primary airway device or as a rescue airway device after unsuccessful ET tube insertion.¹⁶⁻¹⁸ High success rates coupled with low experience reinforcement allows their use in the prehospital setting. The use as a rescue device can “buy time” until additional airway assistance, equipment, and/or expertise can be brought to the patient. Consider using SADs during the initial resuscitation of the sudden cardiac arrest victim in the Emergency Department, as they are quick to insert and allow for progression to uninterrupted cardiac compressions. The SAD can be removed or transitioned to a cuffed ET tube. The primary advantage over ET intubation in a mass toxicology event is time and ease of insertion while wearing a protective garment.¹⁹

CONTRAINDICATIONS

The presence of an intact gag reflex is an absolute contraindication to the use of SADs. The inability to open the patient’s mouth 1.5 to 2 cm will prevent the insertion of most SADs. Trauma to the upper airway is a relative contraindication to placement of these devices. These devices are contraindicated in the patient with a caustic ingestion or airway burns. Many SADs require the patient to be over a certain height and/or weight to be used. Refer to the specific manufacturer recommendations when choosing a SAD and the appropriate size. Dual lumen devices meant to be placed into the esophageal lumen had esophageal disease as a contraindication. Newer SADs fit just into the esophageal entrance and do not traverse the lumen. The dangers of SADs in esophageal diseases and injury are probably overemphasized.

EQUIPMENT

- SADs, various sizes and brands
- Water-soluble lubricant
- Device-appropriate syringe, sized to inflate the cuff
- Oxygen source, tubing, and regulator
- Face mask
- Bag-valve-mask device
- Suction source, tubing, and Yankauer catheter
- Cardiac monitor
- Noninvasive blood pressure cuff
- Pulse oximeter
- End-tidal capnography
- ALS medications
- Advanced airway equipment
- Surgical airway equipment

There are approximately 20 variations of SADs available for clinical use today. They are conceptually divided into three broad categories based on the primary separation between the respiratory and

FIGURE 25-1. The SLIPA.

gastrointestinal tracts. These include cuffless preshaped sealers, cuffed perilaryngeal sealers, and cuffed pharyngeal sealers.^{20,21}

The cuffless anatomic preshaped sealers are flexible molded devices whose shape is based on spiral computed tomography (CT) scan investigations of normal subjects of varying heights and weights.²² These studies created a design template for a device that when inserted blindly will accommodate the “normal” airway in most cases.²² Without an inflatable separation between the respiratory and gastrointestinal tracts there is less flexibility in their design, fit, and use. **These devices offer less potential protection from aspiration of gastric and oropharyngeal contents than other SADs, although some devices do have a gastric sump channel that allows for removal of gastric fluids and air insufflation.** SADs in this category include the Single-Use Liner of Pharyngeal Airway (SLIPA; Hudson RCI, Research Triangle Park, NC) and the i-Gel (Intersurgical Ltd., Berkshire, England). The SLIPA is more commonly used in the Operating Room (Figure 25-1).²³ The i-Gel can often be found in the prehospital and Emergency Department airway equipment (Figure 25-2). The i-Gel performs as well as the LMA-Supreme in both ventilation and protecting the airway from aspiration.²⁴

Cuffed perilaryngeal sealers include the LMA (LMA North America, San Diego, CA) and its many variations, and other laryngeal mask devices. These balloon sealers impact the mucosa of the

FIGURE 25-2. The i-Gel.

airway above the laryngeal inlet itself. The narrowest part of the inflatable lumen is meant to wedge into the upper esophagus, theoretically limiting passive gastric distension during positive-pressure ventilation. Design advances have allowed for device inclusions and upgrades to include a potential gastric channel in the tip of the laryngeal mask that allows for placement of a narrow (typically 14 French or smaller) gastric sump tube for gastric suction and decompression. Refer to Chapter 26 for a more complete and detailed discussion of LMA devices.

Cuffed pharyngeal sealers use a design in which a balloon seals the hypopharynx upstream at the base of the tongue, preventing passive air escape through the mouth and nose. Downstream from the balloon occluding the hypopharynx are numerous ventilation apertures that allow for gas to pass into the tracheal and esophageal lumens. This category of SADs can be further subdivided into those devices with and without a second balloon for the esophagus. Those devices without distal esophageal balloons have a less specific and precise anatomic placement site. This may require more device manipulation to allow for easy ventilation with a theoretical lower aspiration protection. Devices in this category of airways include the Cuffed OroPharyngeal Airway or COPA (Covidien, Mansfield, MA; Figure 25-3), PAexpress or PAX (Vital Signs Inc., Totowa, NJ), and the CobraPLA and CobraPlus (Pulmodyne Inc., Indianapolis, IN; Figure 25-4). The CobraPLA is the only one of these that may be found in the Emergency Department difficult airway cart.

Cuffed pharyngeal sealers with esophageal balloons not only occlude the airway proximally at the base of the tongue, but the esophageal balloon theoretically isolates the esophageal lumen from the respiratory tract. Devices in this category include the Combiscope (Kendall Sheridan, Mansfield, MA), the EasyTube (Teleflex Medical, Kernen, Germany), and the King Laryngeal Tubes (King

FIGURE 25-3. The COPA.

FIGURE 25-4. The CobraPLA. (Photo courtesy of Pulmonary Inc., Indianapolis, IN.)

Systems, Noblesville, IN). All these devices may be found in the Emergency Department difficult airway cart. Refer to Chapter 27 for the complete details of the Combitube and EasyTube. These two SADs are more commonly used in the prehospital environment for a primary or secondary airway and are available in several models.

The King Laryngeal Tubes are made in a variety of sizes and styles (Figure 25-5). They require a single large syringe to fill the esophageal and hypopharyngeal balloons with a preestablished amount of air. Newer models incorporated a gastric sump channel that allows for gastric decompression. An additional advantage is the ability to advance a gastric sump tube in troubleshooting the device with potential kinking of the end of the tube.

The specific equipment for the various SADs will vary slightly with the device used and the size of the device. All SADs are relatively similar. Most of the airway devices are made from silicone and require the liberal use of a water-soluble lubricant to help ease airway placement without mucosal trauma and abrasion. Size-appropriate airway adjuncts must be chosen for the individual patient's anatomy.

PATIENT PREPARATION

The patient should be appropriately monitored with electrocardiography (ECG), end-tidal CO₂ monitoring, noninvasive blood pressure cuff, and pulse oximetry. The patient preparation is the same as

that for orotracheal intubation (Chapter 18). As with any situation where airway manipulation is to occur and the patient's protective airway reflexes are blunted or ablated, a fully functioning suction apparatus must be immediately available. Insertion of the SAD requires an anesthetic depth or degree of unconsciousness similar to that which allows placement and acceptance of an oropharyngeal airway. Successful placement of the SAD is much more likely if the patient is unconscious, premedicated, or sedated. The optimal induction agent should produce jaw relaxation and attenuation of airway reflexes, permitting insertion of the SAD within 30 to 60 seconds of induction and loss of consciousness. A variety of agents are available for induction (Chapter 16). The Emergency Physician experience coupled with the patient's condition will dictate these agents.

Select the appropriate-size SAD based on patient length or weight. Inflate the cuff(s), if present, to ensure that there are no air leaks in the device. Deflate the cuff(s) and leave the air-filled syringe(s) attached to the SAD. Liberally lubricate the SAD with a water-soluble lubricant to aid in its insertion and seating.

TECHNIQUE

The basic insertion technique begins with choosing the appropriate SAD. Gently access the airway. Use the "triple airway maneuver" with head extension, mouth opening, and a jaw thrust to maximize insertion success. Use the nondominant thumb and forefinger in a scissors-like manner to open the patient's teeth, allowing for device insertion. Insert the liberally lubricated SAD along the roof of the mouth and follow the pharyngeal curve at the back of the throat until resistance is noted, markers on the airway tube are at the incisor level, or the airway sealing balloon is situated in the hypopharynx and cannot be advanced any further.²⁵ A rotational technique has been described with either a 90° or 180° rotation that might be more helpful after initial insertion failure by provider.²⁶

Most SADs use a balloon cuff surrounding the air lumen that limits leakage of ventilated gas retrograde into the oropharyngeal cavity and into the environment. The cuffless preshaped pharyngeal sealers do not have a cuff requiring inflation, so no additional syringe is needed. Each cuffed SAD has a range of air required for proper cuff inflation. **Inflate the cuff with the recommended volume of air. Injection of higher volumes of air over recommendations risks SAD migration out of position, airway or esophageal trauma, balloon herniation over the gas passage ports on the device, cuff rupture, and eventual device failure.**

First-pass insertion success for the various SADs depends on the device, the indication for placement, the setting (e.g., prehospital, Emergency Department, or Operating Room), and the provider level performing the procedure. Success rates between 72% and 95% are common when researching the literature. One study showed an 81% first-pass success rate when used as a primary airway and an 84% first-pass success rate when used as a rescue airway.²⁷

A

B

FIGURE 25-5. The King Laryngeal Tubes. A. King LTD models. B. King LTS-D models. (Photos courtesy of King Systems Inc., Noblesville, IN.)

Begin ventilating the patient. Attach a bag-valve device to the SAD airway tube and begin ventilations. Minor manipulations of the SAD may be required to maximize the ease of ventilation in each patient. Slightly rotate or withdraw the SAD with the nondominant hand while ventilating through the device until ventilations are smooth and without resistance. Repositioning of the airway device during its use over time may be required in up to 18% of patients.²⁵

PEDIATRIC CONSIDERATIONS

A SAD can be used for pediatric patients.²⁸⁻³⁶ The SAD is mostly used in adults in the Emergency Department. There are limited studies showing the use in pediatric patients in the Emergency Department. Most studies are based on use in the Operating Room or on simulations. Manufacturers make many of the SADs in pediatric sizes. There is no good reason to not use a SAD as a rescue airway device if an appropriate-sized SAD is present in the Emergency Department. A Combitube or an EasyTube can be used in adolescents (Chapter 27).

ASSESSMENT

The appropriately placed and positioned SAD allows for air movement into the trachea, with varying degrees of potential air leakage into the digestive system during positive-pressure ventilation. Successful placement will allow for relatively effortless gas movement between the patient and the bag-valve device. Successful placement of the SAD is most accurately confirmed by auscultation of bilateral breath sounds, chest wall rise and fall movement with ventilation, and continuous end-tidal CO₂ capnography waveforms. One may gain a sense of correct placement by inserting the gastric sump tubing. The successful insertion of the sump tubing will help verify that the tip of the inserted device has not folded back upon itself, potentially obstructing gas flow.³⁷ The sump tubing has the added benefit of decompressing the stomach.

There does exist the possibility of failure of insertion, migration of the device after correct initial placement, and failure to maintain an adequate internal seal, which prevents effective patient ventilation via positive-pressure ventilation.⁴ **If the patient cannot effectively be ventilated or oxygenated, remove the SAD and return to the BLS skills until additional expertise arrives or another airway option is available and initiated.**

AFTERCARE

Secure the SAD to the patient similar to the process used for ET tubes. This may require device-specific tube ties or straps, twill tape, or adhesive tape. **Periodically reevaluate the SAD function and placement to ensure its position has not changed and it is still providing appropriate oxygenation and ventilation. The SAD may need an occasional position adjustment.** Place the patient on a ventilator. Use a flexible elbow between the SAD and ventilator circuit tubing to prevent any potential for airway displacement during unsupervised use.

The SAD does not protect against aspiration as well as an ET tube. Use the gastric suctioning channels, if present, to decompress the stomach and limit the potential for subsequent aspiration. Replace the SAD with an ET tube or surgical airway once the airway management has migrated from emergent to urgent. The actual method of replacement will be determined by the patient's condition, presence of a "difficult airway," available equipment, and experience of the Emergency Physician.³⁸⁻⁴² Some SADs allow for the blind passage of an ET tube through the airway tube. Other SADs are designed with slit-like apertures that will prevent the passage of an ET cuff.

COMPLICATIONS

There are numerous documented complications associated with the use of SADs.⁴³ One of the most obvious and potentially devastating is the failure to place the device successfully or to obtain a satisfactory seal to allow for efficient oxygenation and ventilation. The incidence of ventilation failure is quite low. Failure to place a SAD appropriately has been estimated to occur in up to 5% of all insertions. The SAD may become displaced during transport or patient movement. Studies on the i-Gel show that device rotation may be required in up to 45% of insertions after correct placement, some minor mandibular manipulation in 23%, and some element of cervical extension to maintain seal in up to 20%. Additionally, up to 5% of patients may require manual securing of tube insertion to correct depth.⁴⁴ Herniation of the epiglottis tip is a documented complication associated with SAD use. It is increasingly noted in anesthesia fiberoptic evaluation of device use and may be of varying clinical significance. Up to 50% of insertions evaluated with fiberoptics may show the tip of the epiglottis in the bowl of the device.⁴⁵⁻⁴⁷ The tip of the King tube may be malpositioned in the airway instead of the esophagus.⁴⁷

There is some controversy in the medical literature as to potential of carotid artery compromise, even with correct anatomic placement. Porcine studies have demonstrated reductions in carotid blood flow and vessel diameter during imaging of use in cardiac arrest. Reduction in carotid blood flow has been demonstrated during routine use in the Operating Room, but the actual clinical impact is uncertain.⁴⁸ There are imaging studies with SADs demonstrating no carotid compression when used during sedation for magnetic resonance imaging procedures.^{49,50}

The insertion of a SAD into the airway can result in mucosal damage and abrasions, especially if not properly lubricated or forcefully inserted. Unilateral vocal cord paralysis can occur secondary to traumatic insertion. Bilateral vocal cord paralysis has not been reported. Dental trauma may occur during the insertion or during maintenance of the airway.

The large and thin cuffs may be torn during use.^{51,52} Overinflation of balloons and cuffs can result in tissue ischemia, erosion, and rupture. Herniation of pharyngeal and airway structures into the SAD has been documented using fiberoptic airway evaluation.⁴⁶ Trapping of the epiglottis in the distal aperture of the SAD may result in edema of the epiglottis. The oropharyngeal balloons have been linked to the development of tongue swelling secondary to venous congestion as a potential complication.^{51,53,54} Overinflation of balloons and cuffs can result in mucosal ischemia, erosion, and lumen rupture. Soft tissue complications (e.g., sore throat, abrasions, and dysphagia) are present after use in 15% to 30% of cases.^{43,55}

Cranial nerve palsies are rare.^{43,55,56} They are being increasingly reported with awareness of their existence. The associated dysphagia, dysphonia, and hoarseness are thought to be related to airway manipulation and soft tissue complications following surgery. Not until a careful evaluation of the patient does one find a cranial nerve deficit. Lingual nerve injury is the most common cranial nerve injury. It is typically self-limiting and may take up to 6 months for resolution. This is thought to be secondary to pressure just below the mucosa of the inner mandible below the roots of the third molar, resulting in tongue numbness and dysgeusia. Hypoglossal nerve damage is related to cuff position. Neurapraxia due to overinflation of the cuff at the level of the greater horn of the hyoid bone results in nerve compression. Recurrent laryngeal nerve dysfunction is most devastating. The recurrent laryngeal nerve is typically compressed bilaterally against the cricoid cartilage where it enters the larynx passing under the inferior constrictor muscles. The resulting nerve dysfunction allows for vocal cord paralysis with the vocal cords stuck in the paramedian position.⁵⁵

TABLE 25-1 Some of the Commercially Available SADs

Name	Manufacturer	Comments
CobraPLA	Pulmonary	Available in adult and pediatric sizes 0.5–6 Accommodates ET tube \leq 8.0 mm inner diameter Disposable single use High-volume, low-pressure oropharyngeal cuff Improved distal curve Large inner diameter Soft and pliable Softer tube and head
CobraPLUS	Pulmonary	Distal gas sampling Same as CobraPLA except contains a temperature monitor
i-Gel	Intersurgical	Accommodates ET tube 6.0–8.0 mm inner diameter Available in adult and pediatric sizes 1–5 Can use fiberoptic bronchoscope through device Cuff matches the anatomy of laryngeal inlet Gastric channel Integrated bite block Noninflating cuff Oral cavity stabilizer Wide airway channel
i-Gel O ₂	Intersurgical	Accommodates ET tube 6.0–8.0 mm inner diameter Available in adult sizes 3–5 Color-coded hook to attach airway strap Similar to i-Gel except supplementary oxygen port
King LT	Ambu	Available in adult and pediatric sizes 0–5 Blind distal tip Insertion marks printed on tube Oropharyngeal and esophageal low-pressure balloons Reusable and disposable single-use versions
King LTS	Ambu	Second lumen allows gastric suctioning with \leq 18 Fr catheter Second lumen is esophageal lumen on posterior Similar to King LT except double-lumen tube

Inappropriate SAD insertion or cuff overinflation in the patient with an intact gag reflex can induce emesis and aspiration.⁵⁷ Both are associated with decreased survival.^{1,58,59} **Always be vigilant to suspect, prevent, and identify aspiration in these patients.** When the SAD permits, provide gastric decompression via suction tube prior to device removal or additional airway manipulation.⁶⁰

SUMMARY

SADs can be effectively used for primary and secondary airway management in the Emergency Department and the prehospital environment. A highly competitive marketplace has allowed for a wide variety of constructions. These devices are relatively simple and quick to insert. They provide an effective bridge between the tracheobronchial tree and the ventilating device. The Emergency Physician must be familiar with their use and limitations.

Laryngeal Mask Airways

Ned Nasr, Gennadiy Voronov, and Luis Sequera-Ramos

INTRODUCTION

The term supraglottic airway (SGA) or supraglottic airway device (SAD) describes a heterogeneous group of airway devices that allow ventilation and oxygenation by sitting above the glottis. The first device of this kind was the laryngeal mask airway (LMA). SGAs are classified according to their characteristics into first-generation and second-generation devices. First-generation devices include the LMA Classic, LMA Unique, LMA ProSeal, LMA Supreme, and the first version of the Air-Q. Second-generation devices generally have an additional conduit for orogastric tube insertion and higher oropharyngeal leak pressures, and some of them allow SGA-guided fiberoptic intubation.^{1,2} SADs result in less cervical spine movement than traditional laryngoscopes.³ This can be useful for prehospital providers and the Emergency Department patient with potential cervical spine injury.

The LMA is a device that fills the gap in airway management between that of endotracheal (ET) intubation and the use of a face mask. It was introduced in the United Kingdom in 1983 by British anesthesiologist A. I. J. Brain. His goal was to develop an airway apparatus that could rapidly overcome an obstructed airway, is simple to use, and is atraumatic to insert. The LMA was approved for use in the United States by the Food and Drug Administration in 1991.

The LMA was designed primarily as a means of providing ventilatory support while avoiding the fundamental disadvantage of the need to visualize and penetrate the vocal cords with an ET tube.⁴ The LMA is introduced into the hypopharynx without direct visualization. It forms a low-pressure seal around the laryngeal inlet and permits positive-pressure ventilation. Pressures of up to 30 cmH₂O may be administered safely with the introduction of the LMA ProSeal (A. I. J. Brain, MD, personal communication). The LMA may be used as a conduit for fiberoptically guided ET intubation or to place an ET tube blindly.⁵ The LMA has come to be viewed as a viable method of airway management, with over 1000 articles and case reports describing the advantages and disadvantages of the device.⁶ A more recent Medline search for articles involving the use of LMAs yielded over 6000 results.

Many disadvantages of the standard LMA became apparent with widespread use of the device. More than 10 years after its introduction, Dr. Brain and colleagues began to work on a new airway system with better intubation characteristics than the standard LMA. The intubating laryngeal mask airway (ILMA) was developed through the aid of analysis of magnetic resonance images of the human pharynx and laboratory testing of ET tubes.⁷ The new and more "anatomically correct" ILMA effects more precise placement. The design of the ILMA also avoids head and neck manipulation and insertion of the intubator's fingers into the patient's mouth, both of which occur during the placement of the standard LMA.^{7,8}

There are approximately nine different models of the LMA (Table 26-1). The term "Laryngeal Mask Airway" is specific to one brand of laryngeal mask devices produced by Teleflex (Research

TABLE 26-1 Some of the LMAs Available Commercially

Name	Manufacturer	Comments
AES Laryngeal Masks	AES Inc.	Similar to LMAs Reusable and single-use versions Made of 100% silicone or silicone cuff and flexible PVC tubes Some models come with a cuff manometer to monitor pressure Available in adult and pediatric sizes depending on model
Air-Q Blocker Laryngeal Mask	Cookgas	Disposable Soft and flexible guide tube next to airway tube Guide tube allows decompression and suction of esophagus and stomach Available in adult sizes 2.5, 3.5, and 4.5 Accommodates ET tube (ETT) \leq 8.5 mm inner diameter Uses blocker tube to suction pharynx and block upper esophagus
Air-Q Laryngeal Mask	Cookgas	Hypercurved Larger mask Resists kinking of mask upon insertion Integrated bite block Reusable and single-use versions Available in adult and pediatric sizes 1.0, 1.5, 2.0, 2.5, 3.5, and 4.5 Accommodates ETT \leq 8.5 mm inner diameter Removal after ET intubation with removal stylet
Air-Q SP Laryngeal Mask	Cookgas	Reusable and single-use versions Self-pressurizing mask requires no inflation port and line Mask inflates with ventilations Mask deflates upon exhalation to positive end-expiratory pressure level Available in adult and pediatric sizes 1.0, 1.5, 2.0, 2.5, 3.5, and 4.5 Accommodates ETT \leq 8.5 mm inner diameter
AuraFlex Laryngeal Mask	Ambu	Disposable Wire reinforced Integrated pilot tube Extra soft cuff Available in adult and pediatric sizes 2–6
AuraGain Laryngeal Mask	Ambu	Anatomic curve Allows decompression and suction of esophagus and stomach Allows \leq 14 French gastric tube for suction Can intubate with ETT through device Allowable size of ETT printed on device Available in adult sizes 3, 4, and 5
Aura-I Laryngeal Mask	Ambu	Disposable Preformed anatomically correct curve Integrated bite block Available in adult and pediatric sizes 1–6 Specifically designed for ETT through device
AuraOnce Laryngeal Mask	Ambu	Disposable MRI safe Preformed anatomically correct curve Molded in one piece with integrated inflation line No epiglottic bars on cuff Allows access of fiberoptic bronchoscope Recommendation to intubate over Aintree device Available in adult and pediatric sizes 1–6
AuraStraight Laryngeal Mask	Ambu	Disposable MRI safe Extra soft cuff Molded in one piece No epiglottic bars on cuff Available in adult and pediatric sizes 1–6
Aura40 Laryngeal Mask	Ambu	Same as AuraOnce except reusable Available in adult and pediatric sizes 1–6
Aura40 Straight Laryngeal Mask	Ambu	No epiglottic bars on cuff Available in adult and pediatric sizes 1–6
LMA Classic	Teleflex	Reusable Available in adult and pediatric sizes 1–6

(Continued)

TABLE 26-1 Some of the LMAs Available Commercially (*Continued*)

Name	Manufacturer	Comments
LMA Classic Excel	Teleflex	Reusable Same as LMA Classic except improved design facilitates ET intubation Available in adult sizes 3–5 Accommodates ETT ≤ 7.5 mm inner diameter
LMA Fastrach	Teleflex	Disposable and reusable versions ET intubation through device Available in adult sizes 3–5 Allows ventilation between intubation attempts Accommodates proprietary ETT from company 6.0–8.0 mm inner diameter
LMA Flexible	Teleflex	Reusable and disposable single-use versions Reinforced tube Available in adult and pediatric sizes 2–6
LMA ProSeal	Teleflex	Double cuff; second cuff allows tighter seal Minimizes posterior pharyngeal wall damage Drain tube separates airway and esophageal tracts Available in adult and pediatric sizes 1–5
LMA Protector	Teleflex	Disposable single use Preformed fixed curve Gastric channel moves regurgitated gastric fluid away from airways Integrated cuff manometer Can use fiberoptic bronchoscope through device Available in adult sizes 3–5
LMA Supreme	Teleflex	Increased safety and ease of use Preformed fixed curve allows easy of insertion Allows higher seal pressures Gastric channel moves regurgitated gastric fluid away from airways Available in adult and pediatric sizes 1–5
LMA Unique EVO	Teleflex	Disposable single use Integrated cuff manometer Integrated bite block Available in adult sizes 3–5
LMA Unique with Cuff Pilot	Teleflex	Soft cuff and tube minimize airway trauma Disposable single use Integrated cuff manometer Soft cuff and tube minimize airway trauma Available in adult and pediatric sizes 1–5
LMA Guardian	Teleflex	Disposable single use Integrated cuff manometer Integrated bite block Not available in United States
Portex Soft Seal Laryngeal Mask	Smiths Medical	Disposable single use Softer cuff than LMAs No epiglottic bars on cuff Wider ventilation orifice than LMAs Integrated inflation line Can use fiberoptic bronchoscope through device Accommodates ETT ≤ 7.5 mm inner diameter Available in adult and pediatric sizes 1–5
Solus satin Laryngeal Mask	Intersurgical	Disposable single use Softer airway tube than LMAs to provide flexibility and ease insertion User information on exposed airway tube Available in adult sizes 3–5
Solus Standard Laryngeal Mask	Intersurgical	Disposable single use Softer airway tube than LMAs to provide flexibility and ease insertion User information on exposed airway tube Available in adult and pediatric sizes 1–5

Triangle Park, NC). Several other manufactures also make laryngeal mask devices. Some of these will also be described in this chapter. The LMA Classic (LMA-C) is the original and most commonly used version. The LMA Classic Excel (LMA-CE) is more durable than the original LMA-C and can be reused up to 60 times. The LMA Unique (LMA-U) is a single-use disposable version of the LMA-C. The LMA

Flexible is a wire-reinforced version of the LMA that is more flexible than the original version and resists kinking. It is used by Anesthesiologists for patients undergoing head and neck procedures. It is not used in the Emergency Department. The LMA Fastrach is a modified version of the LMA that allows ET intubation through the unit. It is also referred to as the ILMA. It allows ventilation during

intubation attempts. Its advantages include the following: it requires no manipulation of the head and neck, it can accommodate up to a size 8 ET tube, it facilitates one-handed insertion, it can be inserted from the patient's side or from above the head, and it can be used in conjunction with fiberoptic intubation. The LMA ProSeal (LMA-PS) features a cuff deflator, modified cuff design, dual tubes, and a bite block. Like the LMA-PS, the LMA Supreme (LMA-S) has a built-in drain tube and bite block. However, the LMA-S is intended for a single use and has a more curved airway tube than the LMA-PS. The LMA CTrach (LMA-CT) includes an insertion site for an ET tube and allows for direct visualization of the larynx using built-in fiberoptics. The Ambu Laryngeal Mask (Ambu LM) has an airway tube that is curved more acutely than that of the LMA-C. This curve follows the anatomy of the upper airway and allows for easier insertion without having to manipulate the head or neck.

The standard LMA, ILMA, LMA-PS, LMA-CT, or Ambu LM may be available in the Emergency Department. The techniques for inserting these devices are discussed in this chapter. The anatomic differences between these devices produce subtle differences in their insertion methods. The indications, contraindications, assessment, and complications associated with these devices are largely identical.

ANATOMY AND PATHOPHYSIOLOGY

The anatomy of the airway is briefly reviewed below (**Figure 26-1**). Refer to Chapter 9 for the complete details of the airway anatomy. The oral cavity is bounded by the hard palate, soft palate, the anterior portion of the tongue, and the reflection of the tongue mucosa onto the floor of the mouth below. The mouth opens into the oropharynx through the oropharyngeal isthmus. The pharynx is a U-shaped tube extending from the base of the skull to the level of the cricoid cartilage, at which point it becomes continuous with the esophagus.⁹ The larynx extends from its oblique opening bordered

FIGURE 26-1. Midsagittal section of the head and neck demonstrating the airway anatomy.

FIGURE 26-2. Sagittal view of the airway demonstrating correct placement of the LMA.

by the aryepiglottic folds, the tip of the epiglottis, and the posterior commissure to the base of the cricoid cartilage.⁹ The esophagus lies posterior to the airway. The tip of the device will lie in the esophagus at the level of the upper esophageal sphincter and directly posterior to the cricoid cartilage when inflated and properly positioned (**Figure 26-2**).

INDICATIONS

The indications for the use of an LMA device parallel the general indications for active airway management.^{10,11} These include the correction of hypoxemia or hypercarbia, the provision of controlled hyperventilation, the provision of a secure airway in the presence of obstruction, and the provision of airway access for pulmonary hygiene and bronchoscopy. An LMA may aid in supporting airways that are difficult to manage as well as being an invaluable aid to blind and fiberoptic intubation.¹² The success rate of correct placement in inexperienced hands approaches 90%.¹³ The LMA is superbly suited for use by medical personnel who have had only a minimal amount of training in airway management.¹⁴

Airway control also facilitates emergent radiographic investigations (e.g., computed tomography [CT] or magnetic resonance imaging [MRI] scans without motion artifact).⁹ The standard LMA contains no ferromagnetic components and is a suitable alternative to an ET tube in many situations. It is ideal for use in patients emergently requiring diagnostic MRI scans. Use of the LMA does not require a metal laryngoscope, which is contraindicated if a patient requires airway management in the MRI suite.

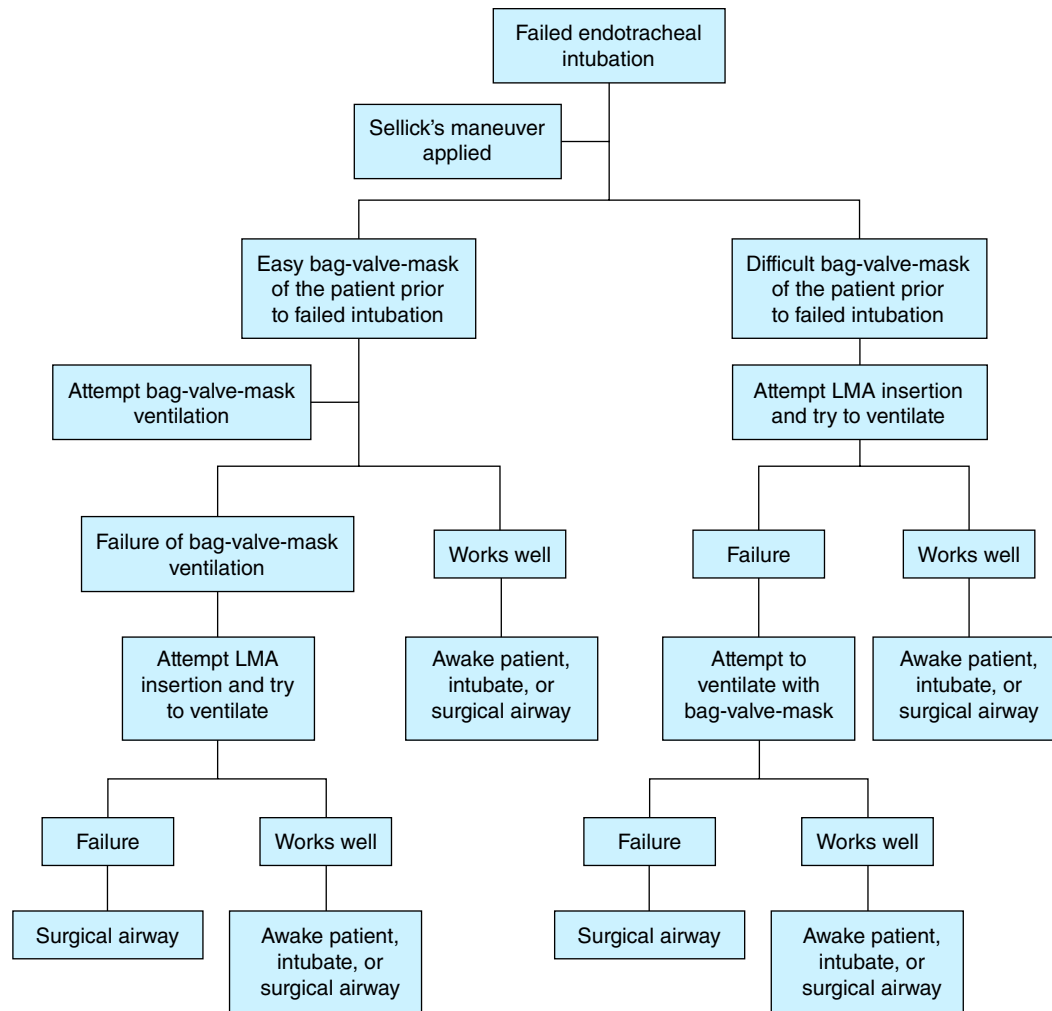

FIGURE 26-3. An algorithm for the use of a LMA in failed orotracheal intubation.

LMA devices may be used in the event of a failed ET intubation (Figure 26-3).^{10,15,16} They have a role in securing the airway presumptively in patients with an “anteriorly” situated larynx, a situation whereby direct laryngoscopy and ET intubation are historically difficult. The LMA is a safe alternative to the esophageal obturator airway, King tube, Combitube, and EasyTube. The LMA has proved to be useful in burn patients requiring repeated dressing changes. The LMA may well be the airway technique of choice for professional singers who require short-term airway management since there is less likelihood of causing vocal cord or laryngeal nerve injury.¹³

There is a conspicuous absence of airway protection from aspiration.¹⁷ The LMA-PS and LMA-S are being marketed as superior to the LMA-C for use in nonfasting patients. These versions feature an improved laryngeal seal for permitting positive-pressure ventilation at pressures up to 30 cmH₂O and a drain tube in tandem with the airway tube. The drain tube facilitates blind insertion of a gastric tube for decompressing the stomach. An introducer aids insertion of the LMA-PS while obviating the need to introduce fingers into the patient’s mouth.

CONTRAINDICATIONS

There are no absolute contraindications to the use of LMAs. However, there are several relative contraindications. These devices should not be used in individuals who are at an increased risk of

regurgitation or aspiration unless the benefit of securing an airway outweighs the risk of aspiration (e.g., when other techniques for securing the airway have failed).¹⁸ This is supported by uncontrolled studies using fiberoptic bronchoscopy, which have shown that the esophagus is visible within the LMA mask in 6% to 9% of patients.¹³ Patients at high risk for aspiration include those with previous upper gastrointestinal surgery, known or symptomatic hiatal hernia, gastroesophageal reflux disease, women more than 10 weeks pregnant, patients with intestinal ileus or peptic ulcer disease, obese patients, or those individuals who are not fasted.^{8,19,20}

The LMA is not an appropriate airway device in emergent situations where cricoid pressure is needed to prevent active or passive regurgitation of stomach contents prior to airway placement. It will not prevent aspiration of stomach contents as efficiently as will a cuffed ET tube. The act of placing an LMA after the application of cricoid pressure (i.e., the Sellick maneuver) has been shown to have a significantly high failure rate.¹³ The LMA-PS and LMA-S feature dual tubes (i.e., airway and drain) as well as a modified cuff designed to provide separation of the respiratory and alimentary tracts. They may prove invaluable in negating this “Achilles’ heel” of the standard LMA.

These devices should not be used in individuals with severe respiratory diseases.^{5,19,20} Patients with airway obstruction at or below the larynx and those with low pulmonary compliance or high airway resistance (e.g., morbid obesity, bronchospasm, pulmonary edema, pulmonary fibrosis, or thoracic trauma) are not appropriate

candidates for LMAs. **The only possible exception is that it can be inserted as a temporary airway rescue device in preparation of another method of ET intubation or a surgical airway.**

Patients must be able to assume the “sniffing” position, analogous to that of individuals positioned for direct laryngoscopy prior to ET intubation. Patients who cannot passively or actively extend their head and flex their neck are not candidates for the LMA-C, LMA-CE, LMA-U, or LMA-S. The ILMA, LMA-CT, LMA-PS with an introducer, and Ambu LM are more appropriate for these patients. Patients should not receive these devices if they cannot open their mouth at least 1.5 cm due to anatomic limitations (e.g., ankylosing spondylitis, severe rheumatoid arthritis, and cervical spine instability).¹³ This is one situation where blind nasotracheal intubation or fiberoptically guided nasotracheal tube placement has an advantage over the LMAs.

The LMA is relatively contraindicated in cases of pharyngeal pathology (e.g., abscesses, caustic ingestions, hematomas, and tissue disruptions). These processes make the use of the LMA difficult. The device may rupture an abscess or a hematoma and cause the patient to aspirate. The use of an LMA after a caustic ingestion can result in perforation of the eroded upper esophageal or hypopharyngeal walls from the pressure of the inflated cuff.

There are numerous cautions that go with the SAD. It should not be used for routine airway management in nonfasted individuals. Trismus or limited mouth opening limits its use. Do not allow high peak ventilatory pressures. Do not use force to place the SAD or a nasogastric tube. Ensure appropriate anesthesia levels. Do not leave the SAD in place for extended times. Either perform an orotracheal intubation, awaken the patient, or perform a surgical airway. Do not reuse an airway meant for single use.

EQUIPMENT

- LMAs, various types and sizes (Table 26-1)
- ET tubes
- Water-soluble lubricant
- Syringes, 10 and 20 mL
- Oxygen source, tubing, and regulator
- Face masks
- Bag-valve device
- Pulse oximeter
- Cardiac monitor
- Noninvasive blood pressure monitor
- Advanced Cardiac Life Support (ACLS) medications
- Advanced airway equipment
- Surgical airway equipment

Many Emergency Physicians have difficulty in picking the appropriate-sized LMA for children. Two formulas have been proposed²¹: (1) the LMA size equals the log of the patient's weight in kilograms divided by 0.6; round this result up or down to the nearest half number; or (2) the cuff inflation volume is five times the LMA size. These formulas are only guides and the LMA size and cuff volume may need to be adjusted to the size of the patient and the air leak.

LMA CLASSIC (LMA-C) AND UNIQUE (LMA-U)

The standard LMA preceded the ILMA by more than a decade. The prototype of the LMA was constructed by forming a shallow mask with an inflatable rubber cuff joined to a tube communicating with the lumen of the mask at an angle.^{4,5} The modern LMA is made of flexible silicone, is completely latex free, and has a more tapered

FIGURE 26-4. The LMA-C. (Photo courtesy of Teleflex, Research Triangle Park, NC.)

appearance. It has a variably sized, internally ridged tube fused at a 30° angle to a spoon-shaped mask with a flexible rim (Figure 26-4).

The LMA-C is a disposable unit that can be used multiple times. It must be sterilized between uses following specific manufacturer recommendations. The LMA-U is similar in construct to the LMA-C. However, the LMA-U is a single-use device. These LMAs are designed to conform to the contours of the hypopharynx with the lumen facing the glottic opening (Figure 26-2).

They consist of an airway tube, inflation line, and mask (Figure 26-4). Overall, they resemble a giant spoon. The airway tube has a large bore and is clear.⁵ The proximal end contains a standard 15 mm airway adapter that can connect to a bag-valve device or a ventilator. A black line along the posterior border is used as a marker for proper positioning. The distal end of the airway tube connects to the mask.

The mask is elliptical in shape (Figure 26-5). The outer rim of the mask contains an inflatable cuff. The tip of the LMA will lie in the esophagus at the level of the upper esophageal sphincter and directly posterior to the cricoid cartilage when inflated and properly positioned (Figure 26-2). The lateral edges of the mask rest in the pyriform fossae. The upper edge rests against the base of the tongue. The LMA provides a seal against the upper esophageal sphincter, aryepiglottic folds, and distal epiglottis to direct air into the trachea and avoid insufflation of the stomach (Figure 26-2).^{5,6}

The distal end of the airway tube opens into the mask. This opening is covered by two vertical aperture bars that prevent the epiglottis from obstructing the lumen of the airway tube (Figure 26-4). **The aperture bars should be cut off prior to inserting the LMA if an ET tube is to be inserted through the LMA.**

A

B

FIGURE 26-5. The distal end or mask of the LMA-C. **A.** The deflated cuff. **B.** The inflated cuff.

The inflation line is used to inflate and deflate the cuff (**Figure 26-5**). The distal end of the inflation line attaches to the upper border of the cuff. The proximal end contains an inflation port and balloon like an ET tube. An air-filled syringe attaches to the inflation port to inflate the cuff.

The correct size of the LMA is based on the patient's weight and is crucial to ensure a proper seal and reduce complications (**Table 26-2**).¹⁸ The distal end assumes a different shape when the cuff is inflated and deflated. The distal end is pentagon-shaped when deflated (**Figure 26-5A**). It is oval-shaped when inflated (**Figure 26-5B**).

LMA CLASSIC EXCEL (LMA-CE)

Although similar in construct to the standard LMA, the LMA-CE has been designed as an "enhanced" version of the LMA-C (**Figure 26-6**). The airway tube has been reinforced, allowing the LMA-CE to be used up to 60 times. It must be sterilized between uses following specific manufacturer recommendations. The inflatable cuff is made of soft silicone to minimize throat stimulation and irritation. The LMA-CE is available in three sizes (**Table 26-3**).

Several modifications have been made to facilitate ET intubation with the aid of a fiberoptic bronchoscope. The airway tube has a 15 mm connector that can be easily removed to allow for access. The airway tube has been designed to accommodate up to a 7.0 cuffed ET tube. It is short enough that the cuff of the ET tube can pass through the LMA-CE and beyond the vocal cords. The mask aperture includes a vertically oriented epiglottic elevating bar, also

known as the EEB (**Figure 26-6**). The EEB is free at the caudal end and fixed at the cephalad end, effectively creating a hinge mechanism. An ET tube passed through the mask aperture swings the EEB backward and elevates the epiglottis away from the path of the advancing ET tube.

LMA FASTRACH (ILMA)

The LMA Fastrach is also known as the intubating LMA or ILMA (**Figures 26-7 and 26-8**). The form of the ILMA was derived from head and neck sagittal MRI studies in normal subjects whose heads were held in a neutral position.⁷ The convex radius of the curve of the silicone-covered steel tube represents a value close to the best-fit curve derived from the MRI studies.⁷ The new prototype consists of an anatomically curved steel tube connected to standard LMA cuff sizes 3, 4, and 5.^{8,19}

The ILMA has several significant modifications that make it different from the LMA-C (**Figures 26-7 and 26-8**). It is available in a reusable stainless steel version and a plastic single-use disposable version (**Figure 26-7A**). Both versions are available in three sizes (**Table 26-4**). The airway tube is stainless steel covered with silicone rubber. The proximal end has a handle fused to the airway tube to facilitate insertion, manipulation, and removal of the ILMA. It is curved to follow the curve of the hypopharynx and position the mask aperture over the glottic aperture. It has a larger diameter of 13 mm versus 9 mm with the LMA.¹⁹ This allows the

TABLE 26-2 LMA-C and LMA-U Size Selection

*The inner diameter in millimeters.

ILMA to accommodate a cuffed ET tube with an inner diameter up to 9.0 mm.^{8,22} It is significantly shorter at 14.5 cm versus 20 cm for the LMA-C.¹⁹

The mask of the ILMA is like that of the LMA with two major modifications. The ILMA contains a ramp inside the distal airway tube as it meets the mask and continues into the mask aperture. It is designed to direct the ET tube into the center of the aperture and into the patient's airway. It also has a large, single, and stiff EEB designed to lift the epiglottis out of the way of the advancing ET tube (**Figures 26-7B and 26-8**). The ILMA avoids hyperextension of the head and neck.²³ This is advantageous in the patient with a potential cervical spine injury.

The ILMA was designed to be used with a wire-reinforced cuffed silicone ET tube with an 8.0 mm inner diameter (**Figure 26-9**).⁸ The ILMA ET tube is available in 6.0, 6.5, 7.0, 7.5, and 8.0 mm sizes. The molded tip allows atraumatic insertion through the vocal cords. It has a transverse black line along its posterior surface. This line serves as a marker to let the intubator know when the tip of the ET tube is positioned at the EEB. This occurs when the ET tube is inserted through the ILMA and the transverse bar is located at the proximal end of the airway tube. While it is ideal to use the wire-reinforced silicone ILMA ET tube, a standard ET tube may also be used.²⁴ The LMA can be inserted in a difficult airway and the patient intubated using the retrograde guidewire technique (Chapter 30).²⁵

LMA CTRACH (LMA-CT)

The LMA-CT is basically an ILMA with built-in fiberoptics that allow direct visualization of airway anatomy (**Figure 26-10**). Two fiberoptic channels lie along the lateral edges of the airway tube.

FIGURE 26-9. The silicone ET tube and pusher used with the ILMA. (Photo courtesy of Teleflex, Research Triangle Park, NC.)

FIGURE 26-10. The LMA-CT. (Photo courtesy of Teleflex, Research Triangle Park, NC.)

These channels merge and exit under the EEB. The properly positioned LMA-CT fiberoptics project an image of the laryngeal inlet directly in front of the mask aperture. A portable color display, the LMA-CT Viewer, attaches magnetically to the top of the LMA-CT airway tube. This allows the intubator to monitor the passage of the ET tube through the vocal cords. The LMA-CT Viewer lies just above the patient's chin and in line with the actual airway anatomy, making intubation easier from a hand-eye coordination standpoint. Images may be recorded and downloaded onto a computer for later documentation and teaching purposes. The use may result in longer intubation times, more maneuvering, and more sore throats than the use of the ILMA, especially in morbidly obese patients.²⁶ One study showed insertion and ventilation rates of 100% and an intubation rate of 90%.²⁷

It is easy to use a LMA CT. A clear view of the vocal cords allows intubation. If the epiglottis is folded on the EEB, perform the up-down maneuver by pulling the LMA out approximately 6 cm and reinserting it with the cuff inflated. The view can be foggy or blurry. Ventilate the patient gently and several times to clear the view. Turn on the light source if the view is dark.

LMA PROSEAL (LMA-PS)

The LMA-PS has been designed to be inserted manually or with the aid of a metal introducer (Figure 26-11). The use of the introducer obviates the need for the intubator to place their fingers in the patient's mouth. The LMA-PS has been modified to allow for ventilation at higher airway pressures. A combination of a softer silicone cuff, an additional rear cuff in larger sizes, and a deeper bowl mask permits higher seal pressures up to 30 cmH₂O. This is approximately 50% higher than with the LMA-C. The LMA-PS provides a tighter seal without increasing mucosal pressure or the risk of complications. It is a reusable device that is available in numerous sizes (Table 26-5).

The LMA-PS features a dual tube (i.e., drain tube and airway tube) system that decreases the risk of rotational dislodgement of the device. The drain tube communicates with the upper esophageal sphincter, allowing for blind insertion of an orogastric tube and for

FIGURE 26-11. The LMA-PS. (Photo courtesy of Teleflex, Research Triangle Park, NC.)

venting of gastric gases and liquids. The drain tube is positioned in the cuff to prevent the epiglottis from blocking the airway tube. The LMA-PS has been designed to decrease the risk of aspiration. Despite this, the manufacturer cautions that the LMA-PS does not provide complete protection against aspiration.

LMA SUPREME (LMA-S)

The LMA-S, like the LMA-PS, is a dual tube system that provides some separation of the respiratory and digestive tracts. The LMA-S is a single-use device and has an airway tube that is more curved and anatomically shaped (Figure 26-12). It has a more rigid airway tube than the LMA-PS; thus, it requires no digital or metal introducer for placement. It can be used for the blind passage of an orogastric tube. The drain tube can help monitor correct positioning of the LMA-S. Gases will audibly leak from the drain tube if the LMA-S does not have a tight airway seal. The LMA-S incorporates a bite block. It is available in numerous sizes (Table 26-6). One study has shown the LMA-S to be equivalent to ET intubation.²⁸

FIGURE 26-12. The LMA-S. (Photo courtesy of Teleflex, Research Triangle Park, NC.)

AMBU LARYNGEAL MASK (AMBU LM)

The Ambu LM (Ambu Inc., Glen Burnie, MD) consists of an airway tube, spoon-shaped mask, and inflatable cuff (**Figure 26-13**). However, the airway tube of the Ambu LM is bent into a smooth curve of approximately 90° to conform to the anatomy of the upper airway and to facilitate easier insertion. Because of this anatomically correct curve, the device can be placed without manipulating the patient's head or neck. The airway tube is D-shaped and easier to grip than other tubes. The distal tip of the Ambu LM is reinforced so that the cuff does not fold over during insertion. The Ambu LM comes in multiple sizes and styles (**Table 26-7**).

KING LARYNGEAL AIRWAY DEVICE (KING LAD)

The King LAD (King Systems, Noblesville, IN) is a disposable, single-use, silicone device like the LMA-C. It is available in two styles (**Figure 26-14**) and a wide range of sizes in each style. The standard model has a curved airway tube, whereas the flexible model has a straight and easily bendable airway tube. The flexible model is reinforced with a wire.

AIR-Q MASKED LARYNGEAL AIRWAY (AIR-Q)

The Air-Q Masked Laryngeal Airway or Air-Q (Mercury Medical, Clearwater, FL) is another commonly used device (**Figures 26-15A and 26-15B**). It is available in a full range of sizes (**Table 26-8**).

TABLE 26-6 LMA-S Size Selection

*The inner diameter in millimeters.

FIGURE 26-13. The Ambu LM.

The airway tube shape and mask inlet have a different shape than the LMA-S. An ET tube can be inserted through the Air-Q like the ILMA. Its shape may make head positioning irrelevant.²⁹

The Air-Q Blocker Masked Laryngeal Airway or Air-Q Blocker (Mercury Medical, Clearwater, FL) has been modified from the Air-Q to include a soft guide tube along the side of the airway tube (**Figure 26-15B**). A lubricated suction catheter or nasogastric tube (up to size 18 French) can be inserted and directed into the posterior pharynx and esophagus to suction secretions. A proprietary suction catheter with an inflatable balloon near the distal end can be inserted through the guide tube. The inflated balloon blocks the upper esophagus to prevent aspiration. The tip of this catheter has multiple holes to allow esophageal venting while the balloon prevents aspiration. The Air-Q Blocker is available in three sizes (**Table 26-8**).

The Air-Q Self-Pressurizing Masked Laryngeal Airway or Air-Q SP (Mercury Medical, Clearwater, FL) is like the Air-Q except for one major structural change. The Air-Q SP has a self-pressurizing cuff that does not require a pilot balloon, inflation line, or syringe to inflate the cuff (**Figures 26-15D and 26-15E**). Positive-pressure ventilation provided by a bag-valve device or ventilator inflates and self-pressurizes the cuff. The Air-Q SP is available in a full range of sizes (**Table 26-8**).

INTERSURGICAL I-GEL

The i-Gel (Intersurgical Inc., East Syracuse, NY) is a second-generation SGA (**Figure 26-16**). It is made from a thermoplastic elastomer (i.e., styrene ethylene butadiene styrene [SEBS]) with a soft durometer and gel-like feel. The softness was designed to match the patient's soft tissues orally, maintain its shape, and facilitate insertion. The noninflating cuff creates a fit with the perilaryngeal and hypopharyngeal structures after placement.³⁰ It has a gastric port (i.e., the second lumen) that allows placement of an oropharyngeal tube. The i-Gel has an integrated bite block. It can also provide a channel for ET intubation.³¹ The i-Gel is available for adult and pediatric patients (**Table 26-9**). Advantages of this SGA include easy insertion, less airway morbidity, and higher airway peak pressures.³² The success of ventilation is decreased with the application of cricoid pressure.³³ The i-Gel is easy to use in infants and adults.^{34,35}

MANOMETERS

Newer versions of the LMA contain a built-in manometer attached to the cuff inflation port.³⁶ This improves the cuff inflation volume administered initially as well as changes to the cuff volume over time. The older versions of the LMA can avoid cuff overinflation by insertion with half of the maximum volume or insertion with the resting cuff volume.³⁶

PATIENT PREPARATION

Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Obtain an informed consent for the procedure if time exists, and place this in the medical record. When performing the procedure on a neonate or child, it is advisable to give the parent the option to leave the room or look away because the procedure can be disconcerting to some parents.

The patient should be appropriately monitored with electrocardiography (ECG), end-tidal CO₂ monitoring, noninvasive blood pressure cuff, and pulse oximetry. The patient preparation is the same as that for orotracheal intubation. **As for any situation where airway manipulation is to occur and the patient's protective airway reflexes are blunted or ablated, a fully functioning**

suction apparatus with a variety of catheters must be immediately available. Insertion of the LMA requires an anesthetic depth like that for the placement and acceptance of an oropharyngeal airway.¹³ Successful placement of the standard LMA is much more likely if the patient is premedicated. **The successful placement of the ET tube is highly dependent on adequate sedation and/or muscle relaxation.** The optimal induction agent should produce jaw relaxation and attenuation of airway reflexes and permit the insertion of the LMA device within 30 to 60 seconds of loss of consciousness. A variety of induction agents may be used.

There is some controversy as to what physical examination findings represent the end point for judging when to insert the LMA. The consensus is that the first attempt at insertion should occur following the loss of the eyelash reflex (i.e., seventh cranial nerve); the jaw should be relaxed at this point.^{20,37} This typically occurs 30 to 60 seconds after administration of the ultra-short-acting induction agents. Some practitioners also rely on the onset of apnea and/or loss of response to verbal stimuli as signs of adequate depth of anesthesia.¹⁶

TECHNIQUES

LMA CLASSIC, UNIQUE, AND CLASSIC EXCEL

Prior to insertion, carefully inspect the cuff for leaks with the cuff slightly overinflated. Completely deflate the cuff so that it forms a smooth wedge shape. The technique for inserting the LMA-C, LMA-U, and LMA-CE is rather simple (**Figure 26-17**). Lubricate the posterior surface of the LMA with a water-soluble lubricant. Care must be taken to avoid lubricating the anterior surface of the device, as the gel might obstruct the distal aperture or trickle into the larynx and provoke laryngospasm.¹³ **Avoid using silicone-based lubricants that may degrade the cuff.¹⁸ Avoid lubricants containing lidocaine as they may provoke an allergic reaction or decrease laryngeal protective reflexes.¹⁸**

Position the patient's head in the sniffing position if not contraindicated. Place the nondominant hand behind the patient's head to stabilize the occiput and slightly flex the neck (**Figure 26-17A**). Allow the patient's jaw to fall open. An assistant may be required to help open it.

Insert the LMA into the oral cavity with the aperture facing but not touching the tongue (**Figure 26-17A**). **It is essential that the leading edge of the cuff be smooth, wrinkle-free, and shaped like a wedge.** This facilitates passage of the cuff around the posterior pharyngeal curvature and into the hypopharynx while avoiding the epiglottis. Place the index and middle fingers of the dominant hand against the junction between the LMA and the cuff (**Figure 26-17B**). Advance the LMA in one smooth movement following the curvature of the pharynx until it enters the hypopharynx (**Figure 26-17B**). The fingers should lie almost horizontally

FIGURE 26-14. The King LAD standard model (left) and flexible model (right).

70–100	4.5	25	8.5	X	X	X

*The inner diameter in millimeters.

when the LMA is properly positioned.³⁸ Grasp and stabilize the airway tube with the nondominant hand. Remove the index and middle fingers of the intubating hand (**Figure 26-17C**). **Slightly advance the LMA further downward until resistance is felt. It is important to not push further.** If difficulty is encountered, a rotational movement of the tube, slight inflation of the cuff, a jaw-thrust maneuver, or the use of a laryngoscope may be helpful.¹³

Inflate the cuff with the recommended volume of air (**Figure 26-17D**). **Do not overinflate the cuff. Inflation usually causes a characteristic outward movement of the airway tube of up to 1.5 cm as the cuff centers itself around the laryngeal inlet.** A slight forward movement of both the thyroid and cricoid cartilages will be noted. **The longitudinal black line on the shaft of the tube should lie in the midline against the upper lip. Any deviation may indicate the wrong size device was used, misplacement of the cuff, or a partial airway obstruction.**¹³ The tip of the LMA cuff lies at the base of the hypopharynx against the upper esophageal sphincter, the sides lie in the pyriform fossae, and the upper border of the mask lies at the base of the tongue pushing it forward when correctly positioned.¹³ The mask may still create a useful airway when grossly malpositioned.¹⁸ Secure the LMA like an ET tube.

LMA PROSEAL

Carefully inspect the cuff for leaks with the cuff slightly overinflated. Completely deflate the cuff so that it forms a smooth wedge shape. The LMA-PS features a cuff deflator. It is a compact, portable instrument for assuring complete removal of air without causing the silicone to wrinkle. Lubricate the posterior surface of the LMA-PS with a water-soluble lubricant. Insert the LMA-PS like that

FIGURE 26-16. The i-Gel. (Photo courtesy of Intersurgical, East Syracuse, NY.)

TABLE 26-9 i-Gel Size Selection

Patient's weight (kg)	i-Gel size	Largest cuffed ET tube size*	Type of patient	Maximum size of nasogastric tube (Fr)

> 90	5	8.0 mm	Large adult	14

N/A, not applicable.

*The inner diameter in millimeters.

described above for the LMA-C. The only difference is that the fingertip should be pushed into the introducer strap at the rear of the cuff.

An alternative method of insertion involves a metal introducer. Head and/or neck manipulation may not be required when using the introducer. Place a properly sized introducer into the strap. Fold the tubes around the convex surface of the introducer and fit the proximal end of the airway tube into the matching slot. Insert the LMA-PS into the oral cavity with the aperture facing, but not touching, the tongue. **The back of the mask must remain in constant contact with the hard palate.** Rotate the LMA-PS inward in one smooth movement following the curvature of the introducer until it enters the hypopharynx and resistance is felt. Grasp and stabilize the airway tube with the nondominant hand. Remove the introducer. Inflate the cuff and secure the LMA-PS. The LMA-PS includes a built-in bite block.

LMA SUPREME

Carefully inspect the cuff for leaks with the cuff slightly overinflated. Completely deflate the cuff so that it forms a smooth wedge shape. Lubricate the posterior surface of the LMA-S with a water-soluble lubricant. Position the patient's head in a semi-sniffing position. The neutral position or a full "sniffing" position may preclude proper placement of the LMA-S.

Insert the LMA-S. Grasp the LMA-S by the connector end. Insert the LMA-S into the oral cavity with the aperture facing, but not touching, the tongue. Briefly rub the mask tip across the palate to lubricate the area. Rotate the LMA-S inward in one smooth movement following the curvature of the pharynx until it enters the hypopharynx and resistance is felt. Directing the distal tip toward the right or left side of the throat may facilitate placement. Grasp and stabilize the airway tube with the nondominant hand. Inflate the cuff and secure the LMA.

LMA FASTRACH (ILMA)

The technique for inserting the ILMA is not very different from that for the standard LMA. It involves a one-handed rotational movement in the sagittal plane with the patient's head supported to achieve a neutral position.⁸ The ILMA may be inserted from above the patient's head or standing to the side of the patient's head. It may be inserted with the right or left hand.

Prior to insertion, slightly overinflate the cuff and check it for leaks. Completely deflate the cuff. Lubricate the posterior surface of the airway tube and the mask liberally. Grasp the ILMA by its handle. Place the patient in the sniffing position if no contraindications exist. Open the patient's mouth with the nondominant hand. Position the ILMA over the patient with the tip of the mask in the

FIGURE 26-17. Insertion of the LMA. **A.** The patient's head is properly positioned, and the LMA is inserted into the patient's mouth. **B.** The LMA is advanced with two fingers. **C.** The LMA is stabilized while the insertion hand is removed. **D.** The cuff is inflated.

patient's mouth (**Figure 26-18A**). Slowly insert the mask while the posterior aspect of the mask remains in constant contact with the hard palate. When the entire mask is inside the patient's mouth and against the hard palate, rotate the ILMA inward along the natural curve of the hard palate and pharynx (**Figure 26-18B**). The airway tube should maintain constant contact with the upper central incisors as the unit is advanced. Stop advancing the unit when resistance is felt. This signifies that the tip of the mask is in the upper esophagus (**Figure 26-18B**).

Inflate the cuff with the recommended volume of air (**Figure 26-18C**). Inflation usually causes a characteristic outward movement of the airway tube, up to 1.5 cm, as the cuff centers itself around the laryngeal inlet. A slight forward movement of the thyroid and cricoid cartilages will be noted. The airway tube

should lie in the midline against the upper central incisors. **Any deviation may indicate the misplacement of the cuff and a partial airway obstruction.** The tip of the ILMA cuff lies at the base of the hypopharynx against the upper esophageal sphincter, the sides lie in the pyriform fossae, and the upper border of the mask lies at the base of the tongue pushing it forward when correctly positioned.

Confirm proper placement of the ILMA. Have an assistant attach a bag-valve device to the proximal end of the airway tube and ventilate the patient. Observe the upper chest rise, auscultate bilateral breath sounds, and observe end-tidal CO_2 monitoring to confirm proper placement. An anterior movement, or bulging, of the cricoid and thyroid cartilages during or after cuff inflation also indicates correct positioning of the ILMA.⁴

FIGURE 26-18. Insertion of the LMA Fastrach or ILMA. **A.** The ILMA is inserted. **B.** The ILMA is advanced until resistance is encountered. **C.** The cuff is inflated. **D.** The ILMA is stabilized and the ET tube is inserted. **E.** The ET tube is advanced into the trachea. **F.** The ET tube cuff is inflated. **G.** The ILMA is carefully removed. **H.** When the ILMA has exited the patient's mouth, grasp and stabilize the ET tube. Completely remove the ILMA.

Insert an ET tube. Lubricate the wire-reinforced silicone ET tube or a standard ET tube liberally. Insert the silicone ET tube into the ILMA until the transverse black line on its posterior surface is at the proximal end of the airway tube (**Figure 26-18D**). The tip of the silicone tube will be just inside the distal end of the airway tube. An assistant can connect a bag-valve device to the silicone ET tube and ventilate the patient if necessary. Make sure that the longitudinal black line on the posterior surface of the silicone ET tube is facing upward.

Slowly and gently advance the silicone ET tube 1.5 cm beyond the transverse black line. **The tip of the silicone tube is just past the vocal cords if no resistance to its advancement is felt.** Continue to advance the silicone ET tube an additional 4 cm (**Figure 26-18E**). The patient can be ventilated by an assistant during this procedure if necessary. Inflate the cuff of the silicone ET tube and ventilate the patient through the silicone ET tube (**Figure 26-18F**). Confirm proper tube placement by the auscultation of breath sounds, observation of chest rise, and end-tidal CO₂ monitoring.

The ILMA should now be withdrawn. Deflate the cuff of the ILMA. Have an assistant remove the bag-valve device and the 15 mm adapter on the proximal end of the silicone ET tube. Withdraw the ILMA by gently reversing the ILMA over the silicone ET tube (**Figure 26-18G**). **Simultaneously apply slight pressure to the proximal end of the silicone ET tube so that it does not become dislodged (Figure 26-18G).** Stop withdrawing the ILMA when the mask begins to exit the patient's mouth. **Grasp the silicone ET tube firmly at the patient's mouth and hold it securely.** Withdraw the ILMA in a smooth curved motion (**Figure 26-18H**). Reattach the standard respiratory connector, ventilate the patient, and reconfirm proper placement of the silicone ET tube.

Some Physicians prefer to use a "pusher" to prevent accidental extubation while the ILMA is being withdrawn. Cut a 25 cm length from a second silicone ET tube. Insert this into the ILMA as it is being removed. Apply slight pressure so it pushes against the first ET tube and prevents it from moving proximally. Remove the ILMA and pusher as a unit when the ILMA exits the patient's mouth. Secure and assess the proper positioning of the ET tube, as mentioned previously.

LMA CTRACH (LMA-CT)

The technique for inserting the LMA-CT is similar to that for the ILMA. The LMA-CT may be inserted from above the patient's head like the LMA-C or standing to the side of their head. Place the patient in neutral position to avoid head extension. The manufacturer recommends only using the LMA-CT with straight, wire-reinforced cuffed silicone ET tubes with a 6.0 to 8.0 mm inner diameter. Standard curved plastic ET tubes may lead to an increased incidence of laryngeal trauma.

Insert the LMA-CT using the technique described for the ILMA. Inflate the cuff with the recommended volume of air and confirm proper placement of the ILMA. Have an assistant attach a bag-valve device to the proximal end of the airway tube and ventilate the patient. Observe the upper chest rise, auscultate bilateral breath sounds, and observe end-tidal CO₂ monitoring to confirm proper placement.

Attach the Viewer by placing the Viewer's socket onto the magnetic latch connector on the LMA-CT. Turn on the Viewer to visualize the glottis. Lubricate the wire-reinforced silicone ET tube. Grasp the LMA-CT by its handle and pass the ET tube back and forth through the airway tube several times to lubricate the entire airway tube. **Do not pass the lubricated silicone ET tube beyond the transverse black line on its posterior surface to avoid obscuring the fiberoptics with lubricant.** Make sure that the longitudinal black line on the posterior surface of the silicone ET tube is facing upward.

Slowly and gently advance the silicone ET tube 1.5 cm beyond the transverse black line. Gripping the handle and lifting a few

millimeters optimizes the alignment of the silicone ET tube and the trachea. The EEB will be seen to rise on the Viewer display as the silicone ET tube passes the mask aperture. Continue to advance the silicone ET tube through the vocal cords. The patient can be ventilated by an assistant during this procedure if necessary. Detach the viewer. Inflate the cuff of the silicone ET tube and ventilate the patient through the silicone ET tube. Confirm proper tube placement by the auscultation of breath sounds, observation of chest rise, and end-tidal CO₂ monitoring. Withdraw the LMA-CT as described for the ILMA.

OTHER LARYNGEAL MASK DEVICES

The Ambu Laryngeal Mask (Ambu LM), King Laryngeal Airway Device (King LAD), Air-Q Masked Laryngeal Airway (Air-Q), and the i-Gel can be inserted and secured like the LMA. An ET tube can be inserted through the i-Gel and Air-Q models. The use of a fiberoptic scope to guide intubation may be more desirable.³¹

ALTERNATIVE TECHNIQUES

Difficulty in insertion of the standard LMA occurs most frequently at the point where the tip of the mask passes just behind the tongue as it changes direction toward the hypopharynx.³⁹ Most of the suggested alternative methods for inserting the LMA involve the negotiation of direction change from the pharynx to the hypopharynx. It has been suggested that a partially inflated mask is easier to place in the correct position.³⁹ Others employ a jaw-thrust maneuver. The mask is positioned firmly and flatly against the hard palate after adequate jaw relaxation has been established. Perform the jaw-thrust maneuver with the nondominant hand while firmly thrusting the mask into place with the dominant hand, in one motion.⁴⁰ The jaw thrust creates a space in the hypopharynx for the mask. The use of a laryngoscope may help facilitate LMA placement, although this reduces the inherent simplicity of the technique of LMA insertion.

One study of the LMA-PS showed that a 90° rotation would improve rates of successful placement.⁴¹ This technique was associated with a lower incidence of mucosal bleeding and sore throat. Insert the device until the entire cuff is inside the mouth. Rotate the LMA-PS 90° counterclockwise and advance it until resistance is felt. Straighten the LMA-PS when it is in the hypopharynx.

A few alternative methods of insertion exist with the ILMA. The metal handle on the tip of the ILMA tube may be used to modify the position of the cuff within the hypopharynx.¹⁹ Pulling back on the metal handle toward the intubator rotates the tube caudally in the sagittal plane. Pushing on the metal handle away from the intubator rotates the tube cephalad in the sagittal plane.

ASSESSMENT

Successful placement of an LMA device is most accurately demonstrated by auscultation of bilateral breath sounds, chest wall movement, and end-tidal CO₂ monitoring (Chapter 19).^{8,19} One may gain a sense of accuracy of placement during insertion. A bulging of the tissues overlying the larynx may be seen during observation of the front of the neck while inserting an LMA. Visualization of this bulge and increased resistance to forward motion of the mask indicates that the device is in the correct position.⁴ Obtain a chest radiograph if an ET tube has been placed through an LMA. Any LMA used for a significant time, 30 to 60 minutes, should be checked to ensure that the LMA has not changed position.⁴² This is best done with a fiberoptic bronchoscope (Chapter 28).

AFTERCARE

The LMA does not protect against aspiration as well as an ET tube. It should be replaced with an ET tube or a surgical airway. The method of securing the airway with a device other than an LMA will be determined by the patient's condition, if the patient has a difficult airway, available equipment, and experience of the Emergency Physician.

COMPLICATIONS

There are numerous documented complications associated with the use of LMAs.⁴³⁻⁴⁵ One of the most obvious of these and potentially the most devastating is the failure to place the device successfully or to obtain a satisfactory laryngeal seal. The incidence of failure to achieve satisfactory ventilation is quite low, even in inexperienced hands. Two large retrospective studies that reviewed 11,910 and 15,795 surgical cases of the standard LMA and unique LMA noted an overall success rate of 99.8% and 98.9%, respectively.^{46,47} Success has been classified as success on one single attempt and overall success. The overall success rate allows up to three attempts to be considered for successful placement. One study demonstrated a 99.5% single-attempt success rate in a retrospective analysis of 1500 cases.²⁰ Most studies indicate correct LMA placement in 88% to 90% of first attempts.¹³ Several studies have found success rates of 90% to 99% for LMAs. A small study showed a first-try rate of 96% using the Ambu AuraGain LMA.⁴⁸ Success rates appear to be higher if a wire-reinforced silicone ET tube is used rather than a standard ET tube.^{49,50} Risk factors associated with LMA placement failure include rotation of the patient after placement, poor dentition, male sex, and increased body mass index.⁵¹ The patients with LMA failure were noted to have a three fold increase in the incidence of difficult mask ventilation.⁴⁶

There are other complications besides failure.⁴⁵ These are divided into minor complications and major complications. The complication rate is defined as events not attributable to the patient's underlying condition, to surgical interventions, or to other interventions. It should be equivalent to that seen during placement of either a Guedel or Berman type oropharyngeal airway. The complication rate when using the LMA is significantly lower than that occurring during direct laryngoscopy and ET intubation. This is potentially due to the intense autonomic nervous system stimulation occurring with the latter procedure.

MINOR COMPLICATIONS

Minor complications are those that may result in significant patient morbidity but usually are not associated with mortality or extremely deleterious outcomes. Stomach inflation can occur during positive-pressure ventilation at pressures greater than 20 cmH₂O for the standard LMA. Cuff herniation secondary to overinflation may result in failure of the cuff to seal effectively. Partial airway obstruction may occur in up to 10% of adults and 25% to 50% of pediatric patients when standard LMA cuffs are examined by fiberoptic bronchoscopy.¹³ Trapping of the epiglottis in the distal aperture of the LMA may result in edema of the epiglottis. Air leaks around the cuff can occur during positive-pressure ventilation at pressures greater than 20 cmH₂O for the standard LMA and 30 cmH₂O for the LMA-PS. Forceful attempts to pass the LMA around the posterior pharyngeal curvature can result in uvular bruising.¹³ Lingual nerve injury, tongue numbness, parotid gland swelling, and hypoglossal nerve palsy are sometimes noted.⁵² Unilateral vocal cord paralysis can occur secondary to traumatic insertion. Bilateral vocal cord paralysis has not been reported. Dental trauma may occur during the insertion or during maintenance of the airway.

MAJOR COMPLICATIONS

Major complications are those from which significant patient morbidity may be expected, including patient mortality. Major complications are exceedingly rare. The LMA may be malpositioned.⁵³ Aspiration occurs in a few patients (0.08%).¹⁷ A report of 11,910 surgical cases where the standard LMA was used had 18 critical events related to the LMA, for an overall incidence of 0.15%.⁴⁷ These events included regurgitation of stomach contents in 0.03%, vomiting of stomach contents in 0.017%, pulmonary aspiration in 0.009%, laryngospasm in 0.07%, bronchospasm in 0.025%, cardiac dysrhythmias in 0.09%, and cardiac arrest in 0.06%. Laryngospasm has been noted in other studies.⁵⁴ While there appears to be a higher incidence of critical events when the device is used for controlled ventilation and positive-pressure ventilation, the incidence has not proved to be statistically significant.

The use of a SAD in swine decreases carotid blood flow.⁵⁵ No studies in humans have been shown to confirm this finding.⁵⁶ If this turns out to be true, an LMA may not be indicated for certain patients.

SUMMARY

A major advancement in airway management was made with the introduction of the LMA. It is superior to a face mask in that it prevents supraglottic obstruction and reduces the likelihood of gastric insufflation.⁵ **The LMA does not provide protection from aspiration.** The LMA-PS and LMA-S, with their dual tube system, may help decrease the risk of aspiration.

The standard LMA has clearly earned a valuable place in the armamentarium of airway management. The technique is easy to learn, easy to teach, and requires no specialized equipment. The LMA causes minimal autonomic nervous system activation and less of a response from the cardiovascular system than with direct laryngoscopy. The LMA is not associated with a risk of esophageal or endobronchial intubation. Both are possible complications following use of the ILMA. The LMA has minimal effects on the intraocular pressure response to airway manipulation. The LMA may be of use in cases of suspected cervical spine injury.

The use of an LMA in place of a face mask avoids many risks, such as injury to the eyes, supraorbital and facial nerves, nose, and lips. There is less risk of hand fatigue than with the bag-valve-mask device. The LMA provides a safer and more secure airway in children and adults than does a face mask, with fewer episodes of hypoxemia as detected by pulse oximetry.¹³ Risk factors for LMA failure include poor dentition, male sex, and increased body mass index.⁵¹

The introduction of the ILMA more than a decade after the standard LMA further defined and expanded the role of this apparatus in airway management. It allows for precise ET tube placement. It is anatomically designed to ensure more accurate placement of the cuff. The placement of the ILMA does not need for the Emergency Physician to be positioned behind the patient's head. There may be a significant place for the ILMA in future airway management algorithms.^{7,57} The advent of the LMA-CT allows for direct fiberoptic visualization of the vocal cords prior to intubation. Newer SGAs such as the Air-Q and the i-Gel follow the same principle and can be effective alternatives for fiberoptic-guided tracheal intubation via an SGA.

Double Lumen Airway Tube Intubation

Joseph Weber and Katie Tataris

INTRODUCTION

The Esophageal-Tracheal Combitube (ETC; Medtronic, Minneapolis, MN) and the EasyTube (EzT; Rusch, Kernen, Germany) are double lumen airway devices that can be blindly inserted into the unconscious and unresponsive patient. The ETC and EzT function to adequately ventilate and oxygenate a patient while simultaneously protecting the airway from aspiration.^{1,2} They are most often used in the prehospital setting by Emergency Medical Technicians not trained in standard orotracheal intubation and by paramedic-level rescuers as an alternative airway device when standard orotracheal intubation fails.³⁻⁶ These devices are used in the Emergency Department primarily as a rescue airway. These are the only two double lumen devices used in the prehospital setting and the Emergency Department. The Emergency Physician should be familiar with these devices so that they can be removed and exchanged with an endotracheal tube if placed in the prehospital setting or if required to manage a difficult airway.

ANATOMY AND PATHOPHYSIOLOGY

The ETC is a double-tube, double lumen, and double-cuffed device (**Figure 27-1**). The ETC starts as two distinct tubes that fuse into one but remain functionally separated by a partition. The shorter clear tube is continuous with the distal open port and is known as the tracheoesophageal lumen. At its distal end is the distal tracheoesophageal cuff, similar to that of an endotracheal tube. It is a high-volume, low-pressure cuff that is inflated through the white inflation port. The longer blue tube is continuous with the eight perforations known as the proximal ports. A large pharyngeal cuff is just proximal to the perforations. This cuff is positioned between the base of the tongue and the palate. It separates the oral and nasal cavities from the remainder of the airway. It is inflated through the blue inflation port.

The EzT is also a double-tube, double lumen, and double-cuffed device with a structure similar to the ETC (**Figure 27-2**). It has several differences in comparison to the ETC (**Table 27-1**). The shorter clear tube ends as a conventional single-lumen 7.5 mm endotracheal tube. The EzT may be used as a primary airway device under direct laryngoscopy. When placed successfully into the trachea, it functions as a 7.5 mm endotracheal tube. If unable to pass it into the trachea, it can be advanced into the esophagus and the patient ventilated through the blue tube.^{7,8} The longer blue tube ends in an open aperture rather than multiple perforations. The EzT is latex free.⁷

Both the ETC and EzT may be inserted blindly into a patient's airway. If the distal tip enters the trachea, the patient is ventilated through the shorter clear tube and the distal cuff prevents aspiration of gastric contents into the trachea. If the distal tip enters the esophagus, the patient is ventilated through the longer blue tube whose proximal ports lie in the hypopharynx and the distal cuff will occlude the esophagus.

Both devices are available in two sizes. The 37 French SA model of the ETC is meant for small adults. The manufacturer recommends its use in patients with a height of 122 to 168 cm (i.e., 4 to 5.5 ft). The 41 French model of the ETC is meant for larger adults with a height of 152 cm (i.e., 5 ft) and greater. Patients in the intermediate range of 152 to 168 cm (i.e., 5 to 5.5 ft) can use either model.

FIGURE 27-1. The Combitube. **A.** Photograph. **B.** Illustration.

A study demonstrated that the 37 French SA model can be used in patients up to 183 cm (i.e., 6 ft, 1 in) in height. The EzT is available in a 28 French model for patients with a height from 90 to 130 cm (i.e., 3 to 4.3 ft) and a 41 French model for patients over 130 cm (i.e., 4.3 ft). The lack of pediatric-sized double lumen airway tubes is a limitation.

TABLE 27-1 Features of Double Lumen Airway Tubes		
Name	Manufacturer	Comments
Combitube	Medtronic	Air-filled syringes for quick cuff inflation included Available in two sizes (37 and 41 French) Can be used as primary airway device or rescue airway device Cannot give medications through tube if placed in esophagus Can ventilate through either tube depending on placement Color-coded and numbered lumens with matching syringes Combines features of endotracheal tube (ETT) and esophageal obturator Disposable and single-use Distal esophageal low-pressure cuff Eight ventilatory holes Includes gastric suction catheter Inserted without a laryngoscope Larger proximal cuff for oropharynx Quick insertion with the head and neck in neutral position Second cuff in esophagus sealed to prevent gastric aspiration When placed in esophagus, allows for passage of gastric suction catheter
Rusch Easy Tube	Teleflex	Air-filled syringes for quick cuff inflation included Available in two sizes (28 and 41 French) Can be used as primary airway device or rescue airway device Can ventilate through either tube depending on placement Color-coded and numbered lumens with matching syringes Combines features of ETT and esophageal obturator Disposable and single-use Includes gastric suction catheter Inserted without a laryngoscope Open second proximal lumen Quick insertion with the head and neck in neutral position Second lumen allows passage of devices (fiberoptic intubation, suction catheter, or ETT exchanger) Single lumen at distal tip

Several attributes specific to these devices contribute to their usefulness in the acute setting. Both are effective as either a primary or backup airway management device. A patient can be ventilated with the tip positioned in either the esophagus or the trachea. Minimal training is necessary. There is no need for a laryngoscope. They are easily inserted with the patient's head and neck in a neutral position. The ETC and EzT are faster and easier to insert than an endotracheal tube in the cardiac arrest patient. This optimizes high-quality compressions and minimizes hands-off time.⁹

The dual lumens and cuffs offer certain advantages. The distal lumen of both allows for gastric suctioning when the tip is placed in the esophagus. The proximal lumen of the EzT is an open lumen rather than perforations, as in the ETC. This allows for the passage of a suction catheter, fiberoptic scope, or endotracheal tube changer with a maximum diameter of 3.99 mm into the trachea.⁷ The cuffs firmly secure the device and make dislodgment unlikely. The proximal cuff can functionally tamponade oropharyngeal bleeding and serve to minimize the risk of aspirating oral debris.¹⁰ These attributes make these devices suitable for rescuers of all skill levels.

The EzT was found to have easier and quicker insertion, higher oropharyngeal leak pressures, and lower peak airway pressures when it was compared to the ETC.¹¹

INDICATIONS

The primary indication for an ETC or an EzT is as a backup device for airway management. It can be used for difficult or failed orotracheal intubations.¹²⁻¹⁸ It should be placed on crash carts for use by individuals not skilled with orotracheal intubation. They can be used when standard orotracheal intubation cannot be performed. This includes limited access to the patient's head (e.g., extrication situations).¹⁹ They should be considered in situations of potential cervical spine injury as the device can be inserted with the patient's head and neck in a neutral position. The ETC is an appropriate device for management of the airway when visualization is limited due to bleeding or secretions. All Emergency Physicians should become familiar with these devices if they are used by Emergency Medical Technicians in their region, and these devices should be considered as alternative airway devices for difficult airways in the Emergency Department.^{10,20} These devices cause less cervical spine movement than direct laryngoscopy.²¹ This makes these devices useful for intubation of trauma patients.

CONTRAINDICATIONS

Certain contraindications exist and should be addressed. **These devices should not be used on patients with an intact gag reflex.** There should be enough time to premedicate the patient and induce anesthesia before inserting the devices if intubation is anticipated. Size limits apply to the ETC and the EzT. The standard ETC cannot be used in patients under 5 ft tall. The smaller ETC SA model cannot be used in patients under 4 ft tall. The EzT cannot be used in patients under 3 ft tall. The ETC cannot be used in patients with a latex allergy. The EzT is latex free and can be used in all patients. Neither device can be used in small children.²²

Their use is contraindicated if the patient has known esophageal disease or an airway obstruction. Patients with known esophageal disease (e.g., strictures, cancer, or victims of caustic ingestions) are at an increased risk of complications (e.g., perforation and failed performance). Patients with known upper airway obstruction (e.g., secondary to congenital disorders, cancer, or other anatomic

abnormalities) are at increased risk for complication and performance failure.

EQUIPMENT

- Gloves, gown, and mask
- Eye protection, goggles, or a face mask with an eye shield
- Pulse oximeter
- Noninvasive blood pressure cuff
- Cardiac monitor
- Intravenous (IV) access equipment
- ETC or EzT kit
- Oxygen source and tubing
- Suction source and tubing
- Water-soluble lubricant
- Bag-valve-mask device
- Advanced Cardiac Life Support equipment and medications
- Surgical airway equipment

The ETC and the EzT are prepackaged in kit form with the dual lumen airway tube, two syringes for cuff inflation, a 90° elbow, and a flexible suction catheter (**Figures 27-3A and 3B**). The ETC kit also contains a vomit deflector that is not routinely used. It may be associated with significant complications and gastric contents directed at the healthcare professional. The suction catheter included is designed to be inserted through the smaller tube and to exit the tracheoesophageal port.

PATIENT PREPARATION

Preoxygenate the patient with a bag-valve-mask device using 100% oxygen. Establish IV access. Apply the pulse oximeter, noninvasive blood pressure cuff, and cardiac monitor. Place the patient supine or in any position that may be required. Prepare the equipment while an assistant is ventilating the patient. Remove the ETC or EzT and equipment from the package. Attach the syringes to their respective ports and inflate the cuffs (**Figure 27-4**). Discard the device and open another kit if a leak of air is present or if the cuff does not inflate properly. Deflate the cuffs and leave the syringes attached to the ports and prefilled with the air needed to inflate

A

B

FIGURE 27-4. The Combitube (A) and the EasyTube (B) with their cuffs inflated. (Used with permission from reference 11.)

on insertion. Liberally lubricate the tip of the device with water-soluble lubricant.

TECHNIQUE

Insert the thumb of the nondominant hand into the patient's mouth and over their tongue (Figure 27-5A). Place the nondominant fingers under the chin. Depress the tongue and open the jaw simultaneously. Remove any dental devices and foreign bodies. Grasp the device with the dominant hand. The curve of the device should be positioned in the same direction as the natural curve of the pharynx (Figure 27-5A). Insert the device into the midline of the patient's mouth. Advance the device in a downward curved motion until the patient's incisor teeth or alveolar ridge lies between the two printed bands of the ETC (Figure 27-5B) or the black stripe of the EzT (Figure 27-6). **Do not insert the device forcefully as significant injury can occur.** If it does not advance easily, redirect it and then reinsert the device. Inflate the pharyngeal cuff with the volume of air marked on the blue port (i.e., 100 mL for the ETC, 85 mL for the ETC SA, or 80 mL for the EzT). The device will withdraw slightly from the patient's mouth as the pharyngeal cuff is inflated. Inflate the distal cuff with the volume of air marked on the white port (i.e., 15 mL for the ETC, 12 mL for the ETC SA, or 10 mL for the EzT).

Begin ventilation through the longer blue tube because most blind intubations follow the natural curve into the esophagus (Figures 27-5C and 27-6). This is easily remembered as "blue is best." Auscultation of breath sounds, symmetric rise of the chest, fogging in the tube for more than six breaths, and lack of gastric insufflation confirm placement within the esophagus and ventilation through the proximal ports or apertures (Figures 27-5C and 27-6). The trachea is intubated if no breath sounds are auscultated and gastric insufflation occurs (Figure 27-5D). Begin ventilation through the shorter clear tube and verify by auscultation the presence of breath sounds.

The device may be too far into the pharynx if breath sounds cannot be auscultated when ventilating through either tube. Deflate the pharyngeal cuff and withdraw the device 2 to 3 cm. Reinflate the pharyngeal cuff. Ventilate through the longer tube and confirm tube placement as noted above.

AFTERCARE

Secure the device. This is accomplished using the standard method of taping or a commercially available endotracheal tube holder. Although there are reports of short-term (e.g., 4 to 6 hours) ventilator use with these devices, it should be replaced with a standard endotracheal tube for long-term ventilation.²³

Several methods for replacing the device are available. The first is to remove the device entirely and intubate the patient orotracheally. Deflate the pharyngeal cuff. Suction the patient's mouth and oropharynx. Tilt the device to the left side of the patient's mouth. Deflate the distal cuff. Remove the device. Intubate the patient orotracheally (Chapter 18).²⁴

Alternative methods of intubation are also possible. Deflate the pharyngeal cuff. Suction the mouth and oropharynx. Tilt the device to the left side of the patient's mouth. Insert the laryngoscope and visualize the tip of the device. Orotracheally intubate the patient if it is in the esophagus. Deflate the distal cuff of the device and remove the device. This method will prevent aspiration if endotracheal intubation is unsuccessful. Instruct an assistant to deflate the distal cuff of the device and remove it slowly if it is in the trachea. Immediately insert the endotracheal tube after the device clears the patient's vocal cords.

The EzT has a significant advantage over the ETC when attempting to replace it with a conventional endotracheal tube. It can be left in place as it is functioning as a 7.5 mm endotracheal tube if the distal end is in the trachea and the patient is being ventilated through the short clear tube. A fiberoptic scope, endotracheal tube changer, or a bougie can be passed through the blue tube and into the trachea if the distal end is in the esophagus and the patient is being ventilated through the long blue tube. The EzT can then be removed and an endotracheal tube passed over the endotracheal tube changer. This cannot be done with the ETC because it has perforations rather than an open aperture.^{7,8}

COMPLICATIONS

Several disadvantages must be kept in mind despite the potential utility of the ETC or EzT in the acute setting. These include the high cost, bulky packaging, and the fact that the ETC detachable "vomit deflector" can expose providers to gastric contents if improperly managed. It is advised not to use the vomit deflector as it can be associated with aspiration. Several risks are also inherent to the insertion and mechanics of the devices. It should be recognized that the presence of a rigid cervical collar can cause great difficulties in the proper placement of this device.²⁵ The device is most frequently inserted into the esophagus. There is a risk of esophageal injury.²⁶

There is no way to suction the trachea with the open distal port in the esophagus. It is important to note that resuscitation drugs that may be administered through an endotracheal tube cannot be given through the device positioned with the tip in the esophagus. Drugs will accumulate in the blind end of the tube or the hypopharynx. Significant soft tissue injury can occur due to the tip of the device or if the cuffs contain too much air.^{25,27} The tip of the device can perforate the esophagus, piriform sinus, or vallecula.

The increased cuff pressure of the ETC versus the EzT can result in mucosal injury.²⁸ An overinflated distal cuff located in the

FIGURE 27-5. Insertion of the ETC. **A.** Positioning of the patient and the physician. **B.** The tube is inserted until the patient's incisor teeth are between the black lines and the cuffs are inflated. **C.** The tube is inserted into the esophagus. The patient is ventilated through the longer tube (1) and air is directed from the proximal ports (arrows). **D.** The tube is inserted into the trachea. The patient is ventilated through the shorter tube (2) and air is directed through the distal port (arrows).

esophagus can compress the trachea and cause an airway obstruction.²⁹ **Always inflate the cuffs with the recommended volume of air and not more.**³⁰⁻³² Prolonged use of up to 4 hours can result in the proximal cuff obstructing the lingual veins and resultant tongue engorgement.³³ This can result in a difficult intubation when exchanging the device for an endotracheal tube. Studies have demonstrated that the lengthy mean insertion speed and the need for multiple steps required has led to increased popularity of single-lumen devices such as the Laryngeal Tube (LT).³⁴⁻³⁶

SUMMARY

The ETC and the EasyTube can adequately ventilate a patient whether they are placed in the esophagus or trachea. They are relatively simple to use and require minimal training. They offer an additional technique to secure the airway in the prehospital and hospital environments. These devices should be familiar to Emergency Physicians who need to exchange these tubes for a definitively managed airway or need to use these devices as alternative tools in the difficult airway patient.

Fiberoptic Endoscopic Intubation

Ruth Moncayo, Alia Safi, and Ned Nasr

INTRODUCTION

The flexible fiberoptic bronchoscope is a useful instrument for the intubation of patients with an anticipated or unanticipated difficult airway.¹ The hallmark of a difficult airway is an abnormal anatomy that precludes the use of the conventional airway management techniques (e.g., face mask and laryngoscope) or maneuverers aimed to align the airway (e.g., jaw thrust and sniffing position).

Any acquired or congenital condition that prevents successful ventilation or intubation by conventional means is a difficult airway. Alternative techniques must be considered for the successful management of these difficult airways. It is imperative in these circumstances to preserve the patient's spontaneous ventilation while safely preparing for a flexible fiberoptic intubation. A unique advantage of the flexible fiberoptic scope is that its malleability and softness allow it to conform to the patient's anatomy and to navigate through the airway with a minimal amount of trauma and discomfort. **Technical problems and failure to successfully intubate patients using this technique are usually due to a lack of familiarity and expertise with the fiberoptic bronchoscope, using it in the wrong clinical setting, or inadequate patient preparation.**

AIRWAY ANATOMY AND INNERVATION

A recognition of the airway's anatomy is of the utmost importance in the performance of a successful fiberoptic intubation by a nasal or oral approach. A more detailed description of the airway anatomy is provided in Chapters 9 (Essential Anatomy of the Airway), 10 (Basic Airway Management), and 18 (Orotracheal Intubation).

It is important to understand the anatomic innervation of the areas through which the fiberoptic bronchoscope will course during the performance of the procedure. This allows a fiberoptic intubation unhindered by the gag and cough reflexes. The fiberoptic bronchoscope passage through the oral cavity will encounter structures innervated by the glossopharyngeal nerve (e.g., the posterior third of the tongue, the vallecula, the anterior surface of the epiglottis, the walls of the pharynx and the tonsils). The glossopharyngeal nerve can be blocked by topicalization of the oropharyngeal mucosa using benzocaine- or 5% lidocaine-soaked pledgets (i.e., applied to the posterior tongue, tonsils, anterior tonsillar pillars [glossopalatal arches] and posterior tonsillar pillars [glossopharyngeal arches]), the inhalation of aerosolized 4% lidocaine, or directly injecting 5 mL of 2% lidocaine. The transoral approach of injection is achieved by using a spinal needle aimed at the base of the posterior pillar of the tonsil (Figure 28-1).² **Do not inject the local anesthetic solution into the internal carotid artery as its runs at 1 inch lateral and posterior to the tonsil.**

The fiberoptic bronchoscope next encounters structures innervated by the internal branch of the superior laryngeal nerve. This nerve originates from a branch of the vagus nerve. It provides sensory innervation to the base of the tongue, posterior surface of the epiglottis, aryepiglottic folds, and the arytenoids. These structures comprise the supraglottic area. The superior laryngeal nerve can be blocked by injecting 2% lidocaine at the cornu of the hyoid bone bilaterally. Finally, the fiberoptic bronchoscope encounters

FIGURE 28-1. Intraoral approach to block the glossopharyngeal nerve. (Used with permission from reference 2).²

structures innervated by the recurrent laryngeal nerve. This is also a branch of the vagus nerve. It supplies sensory innervation to the subglottic area and trachea. It can be blocked by transtracheal injection of local anesthetic solution.

The nasal cavity is innervated by the greater palatine nerve, lesser palatine nerve, and anterior ethmoidal nerve (Figure 203-7). The palatine nerves arise from the pterygopalatine ganglion located posterior to the middle turbinate in the pterygopalatine fossa. They innervate the nasal turbinates and most of the nasal septum. The anterior ethmoidal nerves arise from the olfactory nerve. They innervate the nares and the anterior third of the nasal septum.

FIBEROPTIC TECHNOLOGY

A brief description of the flexible fiberoptic bronchoscope is presented in this section. There are other sources for a more in-depth description of the fiberoptic bronchoscope.³ The principal virtue of the fiberoptic scope is its capacity to transmit an image off axis from the tip of the device to the eyepiece or video camera at the opposite end by means of internal reflections occurring along the length of flexible optic fibers.

The basic structure of the flexible fiberoptic bronchoscope is shown in Figures 28-2A and 28-2B. The major components are the handle, the insertion cord or flexible fiberscope, and a light source. The handle contains the eyepiece for image viewing and a dial to bring the image into focus. A thumb control lever allows deflections of the tip of the fiberoptic bronchoscope in one plane up to 120° up or down.

The insertion cord is composed of thousands of glass fibers, each approximately 8 to 25 μm in diameter. The fibers in the cord transmit an image to the proximal viewing lens. There is a side port along the length the fiberoptic bronchoscope that can be used for the insufflation of oxygen, instillation of local anesthetic or saline solution, limited suction due to the small size of the port, passage

A

of a guidewire, and end-tidal CO₂ monitoring. Any fiberoptic bronchoscope used for intubation should have a length of at least 55 to 60 cm. Consider the diameter of the flexible fiberoptic bronchoscope cord when selecting an endotracheal (ET) tube that fits over it, especially when using small ET tubes (**Table 28-1**).

TABLE 28-1 Flexible Fiberoptic Scopes	4.1–4.9 mm	3.1 mm OD	2.8 mm OD	2.2 mm OD
	OD (adult)	(pediatric)	(pediatric)	(neonatal)

Smallest ETT	4.5	3.5	3.5	2.5

ETT, endotracheal tube; LMA, laryngeal mask airway; OD, outer diameter.

INDICATIONS

The decision to select an awake versus asleep fiberoptic bronchoscope intubation depends on the information collected during the initial assessment of the patient's airway, specifically information pertaining to the ability to mask ventilate the patient. Multiple studies have addressed the impact of certain physical features on predicting difficult or impossible mask ventilation and intubation.⁴ The physical features that have been recognized as being independent predictors of a difficult airway include limited mandibular protrusion, abnormal neck anatomy, sleep apnea or snoring, and a body mass index of 30 kg/m² or greater. Some of the most common contributing factors to be assessed in a patient with a difficult airway are listed in **Table 28-2**.⁵ An awake fiberoptic bronchoscopy has been used successfully in patients at increased risk for dental damage or with a rapidly enlarging neck mass.^{6,7}

TABLE 28-2 The Most Common Contributing Factors to Assess in a Patient to Determine a Difficult Airway

Abnormal anatomy (e.g., congenital craniofacial defects, Pierre-Robin syndrome)
Acromegaly
Burns to face and airway
Cancer of the head and neck
Cervical spine disease (e.g., ankylosing spondylitis or rheumatoid arthritis)
Croup
Decreased thyromental distance
Dental abscess
Epiglottitis
History of difficult intubation
Infection or inflammation that causes airway disruption or rapidly progressing edema
Known difficult intubation
Known difficult mask ventilation
Limited mouth opening
Ludwig's angina
Macroglossia
Micrognathia
Obesity
Obstructive sleep apnea
Pathologic airways (e.g., postradiation fibrosis, stenosis, tracheal deviation)
Positional orthopnea
Risk of aspiration with potential difficult airway
Suspected difficult intubation by direct laryngoscopy
Trauma to face, neck, and/or upper airway
Unstable cervical spine

CONTRAINDICATIONS

The contraindications to fiberoptic bronchoscope intubation are similar to nasotracheal intubation (Chapter 29). Fiberoptic intubation is not recommended for patients who are actively apneic, are vomiting, or have significant oropharyngeal bleeding. Opaque fluids cover the fiberoptic port and prevent adequate visualization through the fiberoptic bronchoscope. Patients who are hypoxic or require assisted ventilation by mask are poor candidates for fiberoptic intubation as the technique may require several minutes to perform. An exception may be made if the patient can be ventilated by an endoscopy mask that has a specialized central orifice for placement of a fiberoptic bronchoscope, by using an elbow connector with a bronchoscopy port attached to a standard face mask, or by using a supraglottic device (e.g., an i-Gel or a laryngeal mask) through which fiberoptic intubation may be performed.^{8,9} Contraindications specific to nasal fiberoptic intubation include coagulopathy, significant midface trauma, severe intranasal pathology, fracture of the cribriform plate, and leakage of cerebrospinal fluid.¹⁰

Relative contraindications to fiberoptic intubation of the airway are situations when instrumentation of the airway may further compromise airway patency (e.g., stridor resulting from airway edema, infection, or epiglottitis). **Some authors advocate fiberoptic intubation as an option to consider in these circumstances, but only by individuals extremely proficient at fiberoptic endoscopic intubation and only with a qualified physician standing by to perform an emergent tracheostomy or cricothyroidotomy if the need arises.**¹¹ It would probably be prudent to establish a surgical airway in the Operating Room under a more controlled setting rather than to attempt a fiberoptic intubation. An emergent tracheostomy or cricothyroidotomy cannot be successfully performed in these patients before complete airway obstruction occurs. **Always be prepared to provide oxygen emergently by another route (e.g., transtracheal jet ventilation) to prevent hypoxic brain damage.**

EQUIPMENT

NASAL ANESTHESIA

- Cotton-tipped applicators
- 4% lidocaine
- 0.05% oxymetazoline (Afrin)
- 4% topical cocaine

OROPHARYNGEAL ANESTHESIA

- 1%, 2%, or 4% lidocaine or benzocaine spray
- Nebulizer device with tubing (**Figure 28-3 and Table 28-3**)
- Cotton 4×4 swabs soaked in 4% lidocaine
- Emesis basin
- Yankauer suction
- Tongue blade

LARYNGEAL ANESTHESIA

- Alcohol swabs
- 10 mL syringes
- 21 gauge needle, 1½ inches
- 2% lidocaine for atomization
- 1% and 4% lidocaine solution
- Nebulizer device with tubing

FIBEROPTIC BRONCHOSCOPY AND INTUBATION

- An assistant
- Fiberoptic bronchoscope with working channel
- Bite block
- Oral airways
- Nasopharyngeal airways
- Light source
- ET tubes, various sizes
- Suction source and catheters
- Cuffed tracheal tubes of various sizes, especially 5 and 7 mm
- Oxygen source
- Oxygen tubing
- Bag-valve device
- Face masks
- Water-soluble lubricant or anesthetic jelly
- Gauze 4×4 squares
- Antisialagogue (e.g., 0.3 to 0.4 mg glycopyrrolate or 0.5 mg atropine)

MISCELLANEOUS SUPPLIES

- Povidone iodine solution or chlorhexidine
- Alternative intubation devices (e.g., difficult airway cart)
- Cricothyroidotomy supplies
- Rapid sequence induction medications
- Crash cart

- Cardiac monitor
- Pulse oximetry
- Noninvasive blood pressure cuff

Atomizer devices are usually not available in the Emergency Department. Many devices are available commercially. These are disposable devices that are single patient use (**Figure 28-3 and**

Table 28-3). A popular device is the MAD line of mucosal atomizer devices (LMA North America, San Diego, CA). They make multiple devices for all topical needs.

Numerous companies make fiberoptic scopes. One popular device in the Emergency Department is the aScope (AMBU Inc., Glen Burnie, MD).^{12,13} It is a single patient use articulating video-scope (**Figure 28-2C**). The aScope uses small digital chips attached

TABLE 28-3 Some of the Commercially Available Atomizers

Name	Manufacturer	Comments
DeVilbiss Model 15 Medical Atomizer	DeVilbiss Healthcare	Adjustable tip Disposable and reusable versions
Enk Fiberoptic Atomizer Kit	Cook Medical	Atomizes through fiberoptic bronchoscope working channel Pressure-resistant oxygen tubing
EZ-Spray	Alcove Medical	Disposable Trigger valve system
LMA MADdy Pediatric Mucosal Atomizer Device	Teleflex	11.4 cm long Attaches to standard syringe Child friendly Comes in various colors and shapes Disposable single-use
LMA Bottle MADomizer Atomizer	Teleflex	10 cm long Disposable single-use tips Reusable bottle
LMA MADgic Laryngo-Tracheal Atomizer	Teleflex	21.6 cm long Attaches to standard syringe Disposable single-use Flexible tube
LMA MAD Nasal-Intranasal Mucosal Atomizer Device	Teleflex	Attaches to standard syringe Disposable single-use

directly at the distal end of the scope. The video signal is electronically conducted to a small portable monitor since the aScope has no eyepiece. Using the plug-and-play monitor is easier than a monocular eyepiece for supervision of others performing the intubation. The unit costs approximately \$200, much less than the cost of a traditional fiberoptic bronchoscope, which costs a minimum of \$8000. There are no cleaning, sterilization, maintenance, and repair costs. The image resolution of the aScope is not equivalent to that of a fiberoptic bronchoscope. However, it is more than adequate to intubate a patient. The aScope can be used as a backup device for the fiberoptic bronchoscope when it is not available.

A disposable sheath for the fiberoptic bronchoscope is available. Numerous companies make an EndoSheath. It is a sterile, single-use, disposable, and microbial barrier that covers the fiberoptic bronchoscope and prevents patient contact. The setup is quick and often takes less than a minute. The proximal end of the EndoSheath has a rubberized hub that grips the proximal end of the fiberoptic bronchoscope. The distal end of the EndoSheath contains an optical quality lens that does not alter the fiberoptic bronchoscope view. It costs approximately \$10. The EndoSheath is removed by pushing the hub off the scope. The EndoSheath comes in a variety of lengths and fits over most fiberoptic bronchoscopes. The EndoSheath eliminates the need to send the fiberoptic bronchoscope out of the Emergency Department for cleaning after its use. The fiberoptic bronchoscope can be used from patient to patient by simply changing the sheath. This eliminates any delays in patient care related to cleaning, processing, and locating the fiberoptic bronchoscope.

PATIENT PREPARATION

Fiberoptic intubation is best performed on awake and spontaneously breathing patients. Rendering the patient unconscious might relax the airway anatomy, distort the airway anatomy, and place the patient at risk for more serious complications (e.g., apnea, airway obstruction, and aspiration of gastric contents).¹⁴ **Proper patient preparation is essential to the successful completion of a fiberoptic intubation.** Proper patient preparation includes counseling the patient, clearing the airway of secretions and blood, judicious sedation, and airway anesthesia (e.g., nasopharynx, larynx, and

trachea).¹⁰ **Counseling is an important and often underestimated part of patient preparation.**¹⁵ Thoroughly explain the necessity for the procedure and the technique. The Emergency Physician can gain the patient's confidence and cooperation, which are invaluable for the performance of a successful fiberoptic intubation.

Apply monitors for electrocardiogram, blood pressure, and pulse oximetry along with an intravenous line for the administration of drugs. Administer supplemental oxygen by nasal cannula, "blow-by," or through the side port of the fiberoptic bronchoscope. Delivering oxygen through the side port offers the additional advantage of blowing airway secretions away from the fiberoptic bronchoscope's tip and can be used to help visualize the vocal cords when redundant tissue is obscuring the view. It has the potential disadvantage of causing gastric distention and rupture.^{16,17} Maintain low oxygen flow to avoid trauma related to oxygen flow through the bronchoscope side port.

The patient may be in a sitting, semirecumbent, supine, or left semilateral position during fiberoptic bronchoscopy.^{18,19} The sitting position will displace redundant pharyngeal tissue anteriorly and open the pharyngeal space by gravity in morbidly obese patients.¹⁵ The use of the sitting position requires the Emergency Physician to stand at the patient's side and inverts the image seen through the fiberoptic bronchoscope. Alternatively, the Emergency Physician can stand on a platform behind the patient to be of sufficient height to correctly perform the procedure. When performing the procedure with the patient in the supine position, the patient's head should lie flat against the table surface with the neck extended (if it is safe to do so). This head position brings the tracheal axis more in line with the nasal and oral passageways and elevates the epiglottis from the posterior pharyngeal wall. The "sniffing position" used for direct laryngoscopy increases obstruction of the glottis by the epiglottis during fiberoptic bronchoscopy and makes the passage of the fiberoptic bronchoscope more difficult.²⁰ Maneuvers performed by an assistant (e.g., the jaw thrust or pulling the tongue forward with a cotton swab) can help to move the pharyngeal soft tissues anteriorly and allow increased maneuverability of the fiberoptic bronchoscope's tip.¹⁰

Instrumentation of the airway may cause the patient to produce copious secretions. This makes an otherwise straightforward fiberoptic bronchoscopy extremely difficult. Bronchoscopy via a "dry" airway devoid of secretions can be accomplished in most instances by administering 0.3 to 0.4 mg of glycopyrrolate. Administer this potent antisialagogue intravenously at least 10 minutes before or intramuscularly 30 minutes before fiberoptic bronchoscopy. Atropine is often more readily available in the Emergency Department than glycopyrrolate. It can be administered in a dose of 0.5 mg intravenously at least 10 minutes before fiberoptic bronchoscopy. The only disadvantage of atropine is that it crosses the blood-brain barrier and can cause central nervous system effects, whereas glycopyrrolate does not. Refer to Chapter 12 for a more complete discussion of these two antisialagogues.

Sedation can be extremely beneficial in gaining the patient's cooperation during the performance of a fiberoptic bronchoscopy. **Sedative drugs, if used at all, should be judiciously titrated to the desired effect with continual assessment of the patient's level of consciousness while avoiding respiratory depression.** Ketamine given in small doses (e.g., 0.5 to 1 mg/kg) and titrating to the desired level of sedation has the advantage of producing minimal respiratory depression and may be preferable to opioids in some cases. Other agents that have been successfully used for sedation during fiberoptic intubations include midazolam, propofol, fentanyl, dexmedetomidine, and remifentanyl.²¹⁻²⁶ Refer to Chapter 12 for a more complete discussion of the pharmacologic adjuncts to intubation. **Avoid sedation if the patient has a tenuous airway, labored respirations, a distended abdomen, or is vomiting.**

AIRWAY ANESTHESIA

Adequate anesthesia of the airway is extremely important when intubating an awake patient.^{27,28} This establishes a quiet larynx devoid of reflexes prior to attempting fiberoptic bronchoscopy. It is especially effective in improving the success rate of individuals who are less experienced at performing fiberoptic intubation. The regional anesthesia techniques employed to anesthetize the airway are a glossopharyngeal nerve block, a superior laryngeal nerve block, and recurrent laryngeal nerve block.

Bilateral blockade of the superior laryngeal nerves will provide effective anesthesia of the larynx and trachea. Prepare a 5 mL syringe with a 25 gauge needle and filled with 1% or 2% lidocaine. Identify the hyoid bone and its superior cornu by palpation (**Figure 28-4A**). Place both index fingers on the neck, one on each side of a point immediately below the lower edge of the mandible and 1 inch antero-inferior to the angle of the jaw (**Figure 28-4B**). Feel the contralateral cornua by gently pushing on one side.

Clean and prep the skin over the superior cornu bilaterally. Insert and advance the needle until it contacts the superior cornu of the hyoid bone. Alternatively, contact with the bone can be made easier by extending the patient's head and gently palpating the hyoid bone with the thumb and forefinger of one hand. By applying gentle pressure to one side, the opposite cornu comes into closer contact with the skin and is subsequently easier to contact with the needle. Walk the needle tip inferiorly and off the bone. Advance the needle 3 to 4 mm and through the thyrohyoid membrane (**Figures 28-5, 28-6, and 28-7**). **Aspirate before injecting the local anesthetic solution to confirm that the needle has not entered the external carotid artery.** Inject 2 to 3 mL of lidocaine. Repeat the procedure on the contralateral side.

The hyoid bone may not be palpated due to obesity, infections, or masses. **Do not attempt a superior laryngeal nerve block blindly.**²⁹ It may be possible to perform the block by using ultrasound (US) to locate the hyoid cornu, thyroid cartilage, vocal cords, cricoid cartilage, and cricothyroid membrane (**Figure 28-8**).³⁰ This will facilitate the performance of the superior laryngeal nerve block and the transtracheal block.³¹

It remains an unresolved controversy whether to abolish the laryngeal reflexes of a patient considered to have a "full stomach." The Emergency Physician must weigh the risk of abolishing the

FIGURE 28-5. The anatomy of the larynx. The syringes demonstrate the superior laryngeal nerve block and the transtracheal block.

FIGURE 28-6. The superior laryngeal nerve block. (Used with permission from reference 2.)

FIGURE 28-7. The recurrent laryngeal nerve block. The needle is inserted and advanced just below the superior cornua of the hyoid bone.

laryngeal reflexes and rendering the patient potentially vulnerable to aspiration versus leaving the laryngeal reflexes intact and thus causing significant discomfort for the patient. Aspiration of gastric contents occasionally does occur in patients with intact laryngeal reflexes when deliberating to proceed with a regional block of the larynx in a patient at risk for gastric aspiration. Instrumentation of the airway in patients with an intact gag reflex can induce vomiting.

The larynx and trachea can be effectively anesthetized by performing a transtracheal injection of 4 mL of lidocaine (**Figures 28-5 and 28-9**).³² Clean and prepare the surface of the skin over the cricothyroid membrane. Prepare a 20 gauge intravenous angiocatheter on a 5 mL syringe containing 2 to 3 mL of sterile saline. Prepare a second syringe containing lidocaine solution. Anesthetize the skin by performing a skin wheal. Insert the angiocatheter on the syringe containing sterile saline perpendicular through the skin in the midline over the cricothyroid membrane (**Figures 28-5 and 28-9**). Advance the syringe until the tip of the angiocatheter is in the trachea. The lumen of the trachea is identified by the loss of resistance. Aspirate air into the syringe, as evidenced by the presence of bubbles in the saline, to confirm that the angiocatheter is within the trachea. **Do not advance the angiocatheter too far, perforate the posterior trachea, and cause a pneumomediastinum.**³³ Securely hold the syringe in place and advance the catheter into the trachea. Securely

FIGURE 28-9. Transtracheal anesthesia of the trachea and larynx. The catheter enters the trachea through the midline of the cricothyroid membrane.

hold the catheter hub at the skin. Withdraw the needle and syringe. Attach the syringe containing lidocaine to the catheter. Briskly inject 3 to 4 mL of 4% lidocaine through the catheter and into the tracheal lumen. This will cause the patient to cough and disperse the local anesthetic solution throughout the trachea and larynx. Remove the syringe and catheter. **The Emergency Physician performing this block should be wearing a gown, face mask, and eye protection to prevent exposure to the respiratory secretions when the patient coughs.**

The nasal passages, pharynx, and larynx can be anesthetized by several other techniques. If the nasal passageways are the anticipated route for intubation, they should be prepared by shrinking and anesthetizing the nasal mucosa. Cocaine (i.e., 4%) applied topically (maximum dose 200 mg) has the advantage of providing profound vasoconstriction and anesthesia to the nasal passageways. Similar effects can be provided by applying 0.25% to 1.0% phenylephrine topically to the nasal mucosa followed by 4% lidocaine via cotton-tipped applicators. Place these applicators gently one at a time through the middle meatus and back to the inferior turbinate. This will anesthetize the posterior palatine ganglion. A nasal passage that accommodates four to five single cotton-tipped applicators will usually allow passage of a 7.0 mm ET tube.¹⁰ The use of three to four sprays of atomized oxymetazoline (e.g., Afrin) into one or both nares is effective in providing profound vasoconstriction of the nasal mucosa.

Once the antisialagogues have taken effect, the tongue and pharynx can be anesthetized. Place a tongue blade on the patient's tongue and apply topical anesthetic spray (**Figure 28-10**). Benzocaine or lidocaine spray will usually provide effective anesthesia for the posterior pharynx within 30 seconds. They can be administered from a commercially available spray container or using an atomizer device (**Figure 28-3 and Table 28-3**). There are reports of methemoglobinemia from the overzealous use of benzocaine.³⁴ Limit its use to several short sprays.

FIGURE 28-8. US to locate the hyoid bone (triangles). Placement of the transducer (*inset*). Transverse US view immediately below the line running through both angles of the mandible. (Used with permission from reference 30.)

FIGURE 28-10. Anesthetizing the posterior oropharynx with atomized lidocaine solution.

Alternatively, the patient can swish 2% viscous lidocaine in their mouth for several minutes to provide effective anesthesia. One of the most effective methods of blocking the glossopharyngeal nerve is the “lollipop method.” Create a lollipop by soaking sterile gauze in lidocaine ointment and taping it to a tongue depressor. Place the lidocaine lollipop into the patient’s posterior mouth while setting up for the fiberoptic bronchoscopy. Advance the lollipop 1 cm every 2 minutes until the patient’s posterior pharynx is completely anesthetized.

Nebulized 4% lidocaine can be administered as an alternative at least 20 minutes prior to fiberoptic bronchoscopy and will usually provide adequate anesthesia of the supraglottic structures. A second alternative is the “spray as you go” technique.³⁵ Once the epiglottis is visualized through the fiberoptic bronchoscope, instill 3 to 4 mL of 2% lidocaine through the working channel of the scope onto the epiglottis and the surface of the vocal cords. This will induce coughing and temporarily obliterate the view of the laryngeal structures. Allow 2 to 3 minutes for the anesthetic solution to exert its effect before proceeding with fiberoptic bronchoscopy.

Place a suction catheter into the oropharynx. This will clear the airway of secretions and blood that can impair the visual image. It will also determine the adequacy of the topical anesthesia for preventing coughing and gagging.

TECHNIQUES

Prepare the fiberoptic bronchoscope. Attach the light source. Check the focus of the image by holding the tip of the insertion cord 1 to 2 cm over a printed page. Adjust the eyepiece until the letters on the image are clear. Note how the image appears as you move toward and away from the page. Briefly use the angulation lever to move the tip of the insertion cord and learn its movements. **The most difficult aspect of mastering fiberoptic bronchoscopy is learning to simultaneously angle the tip, rotate the scope, and advance the insertion cord.**³⁶ It requires repetition and practice to develop these skills before attempting to intubate a patient.

Let the insertion cord hang toward the floor to straighten the inner fiberoptic strands before placing the fiberoptic bronchoscope insertion cord into the ET tube. Identify the plane in which the angulation lever moves the tip. Over time the insertion cord may develop a curve when fiberoptic bronchoscopes are stored coiled in a case. Slightly rotate the fiberscope to the right or left until the angulation of the tip is in the midline plane. Look through the eyepiece and note the position of the directional arrow (▼) on the anterior edge of the image that correlates with midline.

Apply an antifog solution to the insertion cord tip or place the tip in warm water before inserting the fiberoptic bronchoscope into the patient’s nose to prevent fogging of the lens. Warming the ET tube with warm water just prior to placing it on the insertion cord will soften the ET tube and may make its later advancement through the mouth or nares easier.

Apply a thin film of silicone spray or water-soluble lubricant over the insertion cord to facilitate passage of the ET tube over the flexible cord. Insert the flexible insertion cord completely through the ET tube. **Use care and do not get any of the lubricant on the lens tip.** Advance the insertion cord tip until it exits the distal tip of the ET tube. **Do not place the tip of the insertion cord through the Murphy eye of the ET tube.** Lubricate the ET tube liberally.

Estimate the distance from the patient’s mouth to their glottis. Place the tip of the insertion cord by the patient’s ear. Mark the point the insertion cord touches the patient’s mouth. The distance from the mouth to the ear is approximately the distance from the mouth to the glottic opening. Add 3 cm to this length if performing the procedure through the nose.

Hold the fiberoptic bronchoscope in your dominant hand with the angulation lever operated by the thumb and the suction port (if used) covered by the index finger. The other end of the scope should be held between the index finger and thumb of the nondominant hand. Place the nondominant hand at the patient’s nose or mouth. There should be no slack in the fiberoptic bronchoscope between the two hands. The removal of slack from the insertion cord makes more precise rotary movements of the tip possible.

NASAL INTUBATION

Nasal fiberoptic intubation has several advantages over the oral route. Nasal fiberoptic bronchoscopy is usually easier to perform because less angulation of the tip is required for those less experienced at fiberoptic bronchoscopy. Nasal ET tubes are better tolerated by patients and are associated with a lower incidence of accidental extubation. Disadvantages include a higher incidence of bacteremia, middle ear infection, epistaxis, and alar necrosis.¹⁰

Nasal intubation, unlike oral intubation, may produce bacteremia. Provide appropriate endocarditis prophylaxis for those at risk. Mechanical dilation with a finger or nasopharyngeal airways is not necessary.³⁷

Examine the patient to determine which is the most patent nostril. The right side is better than the left and results in decreased epistaxis and faster intubation times.³⁸ Insert and navigate the insertion cord’s tip along the posterior floor of the nares (**Figure 28-11**). Continue to advance the insertion cord and ET tube as a unit until the ET tube enters the oropharynx. This will serve to minimize patient discomfort and the risk of epistaxis early in the procedure. Loss of view and maneuverability of the insertion cord tip occasionally occurs in the oropharyngeal area as the tip encounters the pharyngeal mucosa. Pulling the patient’s tongue forward with gauze, using the jaw-thrust maneuver, or simply advancing the insertion cord a few centimeters further will usually bring pharyngeal structures back into view. Continue to advance the tip of the insertion cord until the epiglottis is visualized (**Figure 28-12**). Maneuver the

FIGURE 28-11. The technique of placing the fiberoptic bronchoscope insertion cord into the nares. Note the position of the ET tube over the proximal portion of the insertion cord.

insertion cord tip with the lever until the glottis comes into view (**Figure 28-13**). Continue to advance the insertion cord tip through the vocal cords and to a point approximately 3 cm above the carina. Advance the ET tube over the insertion cord and into the trachea to the appropriate depth.

The distance from the nares to the epiglottis is approximately 15 to 17 cm. **It is very likely that the insertion cord has entered the esophagus if the 15 cm mark has been passed.** If that is the case, withdraw it to 12 cm and redirect the tip upward with a slight downward movement of the angulation lever.³⁶ This will usually bring the glottic opening into view (**Figure 28-13**). The epiglottis will occasionally obscure the glottic opening. Position the tip of the insertion cord just above the tip of the epiglottis, then advance it a few

FIGURE 28-13. Visualization of the glottis through the flexible fiberoptic bronchoscope just prior to its insertion cord passing through the vocal cords.

millimeters posterior to the epiglottis while angulating the tip of the insertion cord slightly anterior by pressing down on the angulation lever. This will bring the glottic opening into view. Simultaneously rotate, angulate, and advance the insertion cord tip toward and past the vocal cords.

An alternative technique would be to advance the ET tube through the nares until the tip is just past the soft palate (**Figure 28-14**). This is usually at a depth of 10 to 12 cm. The insertion cord is then passed through the ET tube and through the vocal cords. The ET tube is then advanced over the insertion cord into the trachea. This approach has the advantage of bringing the tip of the insertion cord directly midline and toward the epiglottis. This can cause some patient discomfort early in the procedure and may decrease patient cooperation before the insertion cord has entered the trachea. There is the potential for epistaxis to make visualization of laryngeal structures difficult if not impossible. It is difficult to anesthetize the nasal passages completely despite the application of topical anesthesia to the nasal passages. Passage of the ET tube is often the most uncomfortable part of the fiberoptic intubation procedure for the awake patient.

FIGURE 28-12. Visualization of the epiglottis (at the top of the photo) through the flexible fiberoptic bronchoscope.

FIGURE 28-14. The ET tube has been inserted into the nares and advanced into the oropharynx. The insertion cord is advanced through the ET tube.

Emergency Physicians have difficulty passing the insertion cord through the vocal cords on some occasions. There are several causes for this. The tip of the insertion cord may remain angulated and abut against the wall of the trachea. The vocal cords may not be properly anesthetized and may have closed reflexively. The insertion cord tip may be abutting the arytenoid cartilages or the pyriform sinus. If inadequate anesthesia is the cause, inject 2 mL of 2% or 4% lidocaine through the working channel of the insertion cord and wait several minutes for it to take effect. Having the patient inspire deeply will bring the vocal cords into greater opposition. Once the insertion cord tip has passed the vocal cords, bring the tip into neutral position with a light downward motion of the angulation lever.

Advance the insertion cord tip further to bring the bifurcation of the trachea at the carina into view. The trachea can easily be identified anteriorly by the cartilaginous rings and posteriorly by the smooth mucosa of the posterior wall. Advance the ET tube over the insertion cord and into the trachea. The arytenoids or the interarytenoid soft tissues can impede advancement of the ET tube past the vocal cords and into the trachea. If the ET tube advancement is inhibited, withdraw it slightly, rotate it 90° counterclockwise, and reattempt intubation.³⁹⁻⁴¹ If this maneuver fails, rotate the ET tube so that its bevel faces either posteriorly or to the left and laterally. The inability to advance the ET tube occurs with greater frequency when the diameter of the insertion cord is significantly smaller than that of the ET tube or with oral fiberoptic intubation due to the greater curve that the ET tube must assume for it to enter the trachea.³⁶ Consider substituting a smaller ET tube, a spiral-bound ET tube, an ET tube with a flexible tip, or an ET tube that can be guided.^{42,43}

Occasionally, when the trachea is not anesthetized, the patient's subsequent coughing and the associated muscular contractions of the trachealis muscle will collapse the trachea almost completely. This makes it difficult to discern whether the insertion cord tip is in the trachea or whether to advance the insertion cord or ET tube into the trachea. Wait until the trachealis muscle relaxes and then continue with the procedure.

To prevent endobronchial intubation in adults, which can occur with flexion of the head, confirm that the tip of the ET tube is 3 cm above the carina. This is accomplished by advancing the tip of the insertion cord to the carina with the thumb and forefinger of the nondominant hand. Mark the point on the insertion cord where it exits the ET tube. Withdraw the insertion cord until the distance on the insertion cord between the marked point and the tracheal tube connector is 4 cm. While looking through the eyepiece, advance the

ET tube until its tip is visible. This places the tip of the ET tube at approximately 3 cm above the carina.

Difficulty is occasionally encountered while attempting to pass the ET tube through the nares and nasal cavity. This might be caused by a deviated nasal septum, enlarged turbinates, a nasal spur which can tear the ET tube cuff, or nasal polyps. Selection of an ET tube that is too large, inadequate lubrication, or failure to presoften the ET tube can be the cause. Reattempt insertion with a well-lubricated, presoftened ET tube that is 0.5 to 1.0 mm smaller. Alternatively, try placing a 5.0 mm inner diameter (ID) ET tube in a 7.0 mm ID ET tube, as discussed below.

ORAL INTUBATION

Begin by noting any loose or broken teeth. Ensure an adequate sensory block by the absence of a gag reflex. Insert an oral intubating airway into the patient's mouth. These devices are placed in the patient's mouth like any other oral airway. They allow for the midline passage of the insertion cord and protect the delicate fibers within it from the patient's teeth.

Technical problems exist in attempting oral fiberoptic intubation. Oral fiberoptic intubation requires that the insertion cord tip traverse a more acute angle to reach the vocal cords than it would by the nasal route. Maximally extending the patient's head at the atlantooccipital joint will bring the oropharyngeal and laryngeal axes more closely in line if it is safe to move the patient's neck. This maneuver will reduce the angle that the insertion cord tip must traverse.

The ET tube becomes hung up on the vocal cords more frequently than with the nasal route. A technique believed to significantly improve the first-time pass rate with oral fiberoptic bronchoscopic intubation is to pass a lubricated 5.0 mm ID ET tube through a 7.0 mm ID ET tube that has been cut to 24 cm. This should leave 2 cm of the 5.0 mm ID ET tube protruding from the distal end. It is believed that the close approximation of the diameters of the 5.0 mm ID ET tube and the fiberoptic bronchoscope allows easier passage of the scope. After the 5.0 mm ID/7.0 mm ID ET tube complex is in place, withdraw the 5.0 mm ID ET tube, and leave the 7.0 mm ID ET tube in the trachea.⁴⁴

A face mask with a fiberoptic bronchoscope adapter can be used (**Figure 28-15**). This allows an assistant to hold the face mask and ventilate the patient during the fiberoptic bronchoscopy. High-flow nasal oxygen can be administered to those spontaneously breathing. This can be alone or in addition to the face mask.

FIGURE 28-15. A fiberoptic bronchoscopy adapter that is added to a face mask.

ALTERNATIVE TECHNIQUES

Alternative techniques that have been shown to be as effective as fiberoptic intubation for intubating patients with unstable cervical spines include the Bullard laryngoscope and the lighted stylet.^{45,46} Blind nasotracheal intubation is as successful as nasal fiberoptic intubation in anesthetized patients with unstable cervical spines.⁴⁷ The Glidescope, a video laryngoscope, causes less cervical spine movement than direct laryngoscopy.⁴⁸

A combined technique using oral fiberoptic intubation through a laryngeal mask airway (LMA) or alternative supraglottic airway can be extremely helpful in instances where there is severe oropharyngeal bleeding or when direct laryngoscopy is not possible.^{8,49-51} After confirming successful placement of the LMA, place a self-sealing bronchoscopy elbow over the proximal end of a 6.0 mm ID ET tube.⁵² Advance the ET tube tip through the LMA until the LMA grille is encountered and resistance is felt. Inflate just enough air into the ET tube cuff to provide a seal for positive-pressure ventilation via the ET tube. Advance the insertion cord through the ET tube and into the trachea under direct visualization. Deflate the ET tube cuff. Advance the ET tube over the insertion cord and into the trachea until the ET tube adapter meets the adapter of the LMA. Inflate the ET tube cuff and confirm ventilation through the ET tube.

Because standard ET tubes are not long enough to allow removal of the LMA, longer ET tubes have been developed. If you do not have access to a specially made ET tube, use a nasal Rae tube, which is 6 cm longer than a standard ET tube. If a longer ET tube is not available, another ET tube can be temporarily lengthened by removing the adapter of the 6.0 mm ID ET tube and placing the tip of a 5.0 mm ID ET tube into the lumen of the 6.0 mm ID ET tube. This maneuver lengthens the ET tube enough that the LMA cuff can be deflated and withdrawn, leaving the 6.0 mm ID ET tube correctly placed in the trachea. Additionally, ventilation can be maintained the entire time simply by using a bag-valve device connected to the 5.0 mm ID ET tube adapter. After removing the LMA, remove the 5.0 mm ID ET tube from the 6.0 mm ID ET tube, replace the adapter, and resume ventilation.⁵³ **Always confirm by fiberoptic bronchoscopy that the ET tube is correctly positioned after removing the LMA and establishing ventilation.**

ASSESSMENT

The placement of an ET tube should be followed by an assessment to ensure its proper positioning (Chapter 19). This includes visual inspection of chest rise and lack of abdominal movement with ventilation, fogging in the ET tube for at least six breaths, auscultation, and end-tidal CO₂ monitoring. This should be followed by a chest radiograph to confirm proper positioning of the ET tube within the trachea.

AFTERCARE

The steps of ensuring proper placement of the ET tube and securing the tube are the same as for any patient who has undergone orotracheal intubation (Chapter 18).

COMPLICATIONS

Many of the complications associated with fiberoptic intubation are the same as those seen with direct laryngoscopy (Chapter 18). The most severe complication is hypoxemia from a prolonged procedure or delays due to inexperience. Use high-flow nasal oxygen to prevent hypoxemia.⁵⁴ Use the suction channel on the bronchoscope to provide oxygenation to the patient during the procedure. Epistaxis can be minimal or significant enough to complicate the procedure.

Bleeding can be minimized by using the correct ET tube size and pretreatment with a nasal vasoconstrictor and anesthetic. Failure to intubate can be due to narrow nasal or airway passages, blood or vomitus limiting the fiberoptic field of view, or inexperience. Oxygen insufflation into the pharynx and esophagus works its way into the stomach. This can distend the stomach and cause it to rupture.⁵⁵

While the insertion cord is passed through the glottis and into the trachea under direct vision, the ET tube is passed blindly over the insertion cord tip. It is possible to cause injury to the arytenoids resulting in permanent hoarseness if the ET tube bevel faces anteriorly. A randomized controlled trial showed no difference in the incidence of vocal cord injury for nasotracheal fiberoptic intubation versus orotracheal intubation.⁵⁶ The ET tube may become blocked in the nasal cavity or larynx, cause epistaxis, result in a nasal turbinate fracture, and tear the ET tube cuff.^{10,57} Sinusitis and otitis media are known complications from nasal intubation.¹⁰

SUMMARY

Awake intubation under direct visualization in spontaneously breathing patients by the oral or nasal route is possible with the fiberoptic bronchoscope. Intubation by means of the fiberoptic bronchoscope is an option to consider when direct laryngoscopy is difficult or impossible. Awake fiberoptic intubation may be preferable in some instances to other techniques that render the patient unconscious and apneic. Fiberoptic intubation is associated with a high success rate when performed by appropriately trained individuals. Training and practice are required to develop and master the necessary skills.⁵⁸ Appropriate patient selection, preparation, and patience are essential for a safe and successful fiberoptic intubation.

The benefits of performing regional anesthesia of the oropharynx, larynx, and trachea prior to fiberoptic intubation are a quiet visual field and improved patient acceptance.

Oral fiberoptic intubation may be performed in conjunction with an LMA. In most instances, fiberoptic intubation is an extremely safe and effective means of securing the airway. Be prepared to implement an alternate plan for securing the airway and for providing oxygen in the case of procedural failure or sudden deterioration of the patient's condition.

Nasotracheal Intubation

Ned F. Nasr, Abed Rahman, and Isam F. Nasr

INTRODUCTION

Nasotracheal intubation is a relatively simple procedure that is performed rapidly without the aid or risks of neuromuscular blockade.¹ This method of intubation is sometimes favored in difficult airway cases, especially when oral access is limited or impossible. Such conditions include trismus, oral injuries, and obstructive oral processes such as angioedema. Nasotracheal intubation is also the method of intubation preferred by some for acute epiglottitis.² **It is the most common method of inducing anesthesia for oral surgery cases to ensure optimal surgical access.**³

Nasotracheal intubation is well tolerated by most patients and produces less reflex salivation than orotracheal intubation, thus leading to fewer attempts at self-extubation. The nasotracheal tube is more easily stabilized and is generally easier to care for than an orotracheal tube. This method prevents biting of the tube by the patient and manipulation by the patient's tongue.^{2,4}

INDICATIONS

Nasotracheal intubation is indicated in any patient with spontaneous respirations, especially those whose period of intubation is anticipated to be brief.¹⁻⁴ It is indicated in patients who are unable to lay supine due to respiratory distress from severe asthma, chronic obstructive pulmonary disease (COPD), or congestive heart failure. It is also indicated in patients who are unable to open their mouths due to facial trauma, mandibular trauma, or trismus. Nasotracheal intubation can be performed in patients with limited airway patency due to obstruction from neoplasm or tongue swelling. Nasotracheal intubation is an appropriate method of intubation in patients who require neck immobilization for suspected cervical spine injuries, patients unable to move their necks due to cervical kyphosis, patients with severe cervical arthritis limiting neck movement, or patients with postradiation fibrosis. Because they are often intubated for a short time, patients with severe alcohol intoxication or drug overdose whose level of consciousness is decreased are good candidates for nasotracheal intubation.^{1,2,4} Nasotracheal intubation may be performed in patients who have contraindications to the use of succinylcholine (Table 16-2).

CONTRAINDICATIONS

Nasotracheal intubation is contraindicated in patients with apnea, severe facial or maxillofacial fractures, basilar skull fractures, head injury with an elevated intracranial pressure, penetrating neck injury, nasal obstruction, recent nasal surgery, or nasopharyngeal obstruction; patients receiving thrombolytics or parenteral anticoagulants; and in the presence of a coagulopathy.¹⁻⁵

Nasotracheal blind intubation should not be performed in neonates, infants, or very young children. The more anterior and cephalic position of the airway in these age groups makes blind passage of an endotracheal tube (ETT) almost impossible. A patient must provide a degree of cooperation during the procedure. A crying, kicking, and struggling child who must be restrained is not a candidate for nasotracheal intubation.

EQUIPMENT

- Nasal mucosa vasoconstrictor (e.g., 4% cocaine, 0.05% oxymetazoline, 0.25% phenylephrine)
- Nasal mucosa anesthetic (e.g., viscous lidocaine, cocaine, benzocaine spray, xylocaine spray)
- Nasal atomizer (Table 29-1 and Figure 29-1)
- Nasopharyngeal airways, multiple sizes
- Laryngoscope handle
- Laryngoscope blades, various sizes and types
- ETTs, various sizes (average female 7.0 to 7.5 and average male 7.5 to 8.0)
- Endotrol tubes, various sizes (Mallinckrodt Medical, St. Louis, MO)
- Magill forceps or Tylke forceps (Figure 29-2)
- Suction apparatus

TABLE 29-1 Some of the Nasal Atomizers Commercially Available

Name	Manufacturer	Comments
DeVilbiss Model 15 Medical Atomizer	DeVilbiss Healthcare	Disposable and reusable versions Adjustable tip
Enk Fiberoptic Atomizer Kit	Cook Medical	Pressure-resistant oxygen tubing Atomizes through fiberoptic bronchoscope working channel
EZ-Spray	Alcove Medical	Disposable Trigger valve system
LMA MADdy Pediatric Mucosal Atomizer Device	Teleflex Medical	Disposable single-use Comes in various colors and shapes Child friendly Attaches to standard syringe 11.4 cm long
LMA Bottle MADomizer Atomizer	Teleflex Medical	Disposable single-use tips Reusable bottle 10 cm long
LMA MADgic Laryngo-Tracheal Atomizer	Teleflex Medical	Disposable single-use Attaches to standard syringe Flexible tube 21.6 cm long
LMA MAD Nasal-Intranasal Mucosal Atomizer Device	Teleflex Medical	Disposable single-use Attaches to standard syringe
MADomizer Caps	Wolfe Tory Medical	Disposable bottle and pump No need for compressed air

- Topical anesthetic (e.g., 4% cocaine or 2% lidocaine with epinephrine)
- Gauze strips
- Water-soluble lubricant or anesthetic jelly
- Bag-valve device
- Face mask
- Oxygen source and tubing
- Fiberoptic laryngoscope (Chapter 28)
- Video laryngoscope (Chapter 21)

Atomizer devices are usually not available in the Emergency Department. Many devices are available commercially. These are single patient use, disposable devices (Figure 29-1 and Table 29-1). A popular device is the MAD line of mucosal atomizer devices (LMA North America, San Diego, CA). They make multiple devices for all topical needs.

The McGill forceps is the standard used by most institutions (Figure 29-2A). The forceps are used to introduce the ETT into the patient's trachea from the hypopharynx under direct visualization. It is available in infant, child, and adult sizes. The forceps tip's twin blades for gripping are offset with serrated tips. It is curved at an oblique angle between the handles and the blades to prevent the view of the patient's airway from being obscured. The ends of the blades are rounded to minimize trauma.

The Boedeker forceps (Karl Storz Endoscopy, El Segundo, CA) is an alternative to the McGill forceps (Figure 29-2B). It is also curved but does not put the working end into the view of the intubator.

The Tylke forceps (Rodinia LLC, Jupiter, FL) is a new device that is simple to use, safe, and an effective alternative to the McGill forceps (Figure 29-2C). It allows nasotracheal intubations 25% of the time and reduces the possibility of torn cuffs and vocal cord trauma. The circular tip of the Tylke forceps prevents losing control of the ETT, without having to grip the ETT firmly, and allows the aiming of the ETT in the desired direction. The twist and bend of the Tylke forceps prevent the vocal cords from being visually obstructed and provide improved access to the trachea. It is available in three sizes (i.e., adult, adolescent, and child).

(Photo courtesy of Karl Storz Inc.) **C.** The child, adolescent, and adult versions of the Tylke forceps. (Photo courtesy of Rodinia LLC.) **D.** The Tylke forceps easing an ETT tube through the vocal cords. (Photo courtesy of Rodinia LLC.)

Use of the Tylke forceps is simple (**Figure 29-2D**). Insert the Tylke forceps into the mouth. Grab the ETT from the right side or slide the Tylke forceps over the tip of the ETT with the forceps vertical. Another method is to tilt the Tylke forceps left 90° to encircle the ETT from the top and then return the Tylke forceps to a vertical position. Aim the Tylke forceps at the vocal cords and have an assistant advance the ETT through the vocal cords and into the trachea. Pull the Tylke forceps back to the oropharynx while loosely wrapped around the ETT. Rotate the hand to the right, open, and disengage the Tylke forceps. Carefully remove the Tylke forceps from the mouth.

PATIENT PREPARATION

Explain the risks, benefits, and potential complications of the procedure to the patient and/or their representative if time permits. All procedural steps should be clearly outlined, with the understanding that an orotracheal intubation may be necessary should the Emergency Physician fail to secure the airway nasotracheally. Since this is a lifesaving procedure, a signed consent may not be necessary, but a procedure note should be included in the medical record.

Prepare the patient with preoxygenation, hemodynamic monitoring, pulse oximetry, and vascular access. Place the patient supine and in the “sniffing” position if there is no suspicion of a cervical spine injury. If the patient needs to remain sitting due to respiratory distress, also place them in the sniffing position.

Examine the patient’s nostrils. Choose the larger and more patent nostril for the intubation. The choice of which nostril to use is not an exact science.⁶ Look at and into each nostril and determine which one is more patent. Estimate the airflow through each nostril.^{7,8} Occlude one nostril and instruct the patient to exhale with their mouth closed. Repeat the process with the other nostril. Ask the patient which nostril they feel is more patent. This test can be repeated after the application of a vasoconstrictor agent. **There is some evidence that the right nares is preferred due to faster intubation times and less epistaxis.**^{5,9,10}

Prepare the mucous membranes.¹¹ Apply a topical vasoconstrictor to shrink the nasal mucosa followed by a topical anesthetic to the nasal mucosa. It is best to perform this using a nasal atomizer (**Table 29-1 and Figure 29-1**). Use cotton soaked pledgets if an atomizer is not available. Cocaine is preferred, if not contraindicated,

because it is a single agent that acts as both a vasoconstrictor and an anesthetic. Commonly, an equal mixture of 2 to 3 mL of 1% lidocaine and oxymetazoline 0.05% is sprayed or swabbed in the nasal mucosa. Dilate the nasal passage by serial dilation. Liberally lubricate a series of increasingly larger-size nasopharyngeal airways. Insert and then remove the smallest nasopharyngeal airway. Continue to insert and remove each successively larger nasopharyngeal airway until the nasal passage is dilated. This procedure can take 2 to 3 minutes. If time is an issue, insert a gloved and lubricated pinky finger into the nostril to dilate it. Serial dilation of the nasal passages can be bypassed in patients with large nostrils for routine nasotracheal intubations of healthy adults.¹² Apply a topical anesthetic spray to the palate and oropharynx.

Choose an ETT appropriate for the patient. The proper size tube should be at least 0.5 to 1.0 mm smaller than the size chosen for orotracheal intubation of the same patient. Soften the ETT by placing it in warm saline or warm water before use to reduce epistaxis and nasal damage if possible and time permits.¹³ Apply a 10 mL syringe to the inflation port and inflate the cuff. Check the integrity of the cuff. Deflate the cuff and leave the syringe attached. Lubricate the ETT.

TECHNIQUES

BLIND PLACEMENT OF AN ETT

The technique of blind nasotracheal intubation was first described by Magill in 1930. The technique essentially remains the same with some modifications to increase the success rate and limit complications. This technique is technically more difficult than the placement under direct vision described below. **Its major advantages are that the patient’s mouth does not have to be opened and minimal to no cervical spine movement is required.** This procedure may be performed while the patient is sitting or supine. Prepare the patient as mentioned previously.

Stand to the right side of the patient’s bed and facing them. Insert the ETT into the nostril with the bevel facing the septum (**Figures 29-3 and 29-4A**). Insert the ETT concave side down if the patient’s right nostril is being used (**Figure 29-3A**). Insert the ETT concave side up if the patient’s left nostril is being used (**Figure 29-3B**). Advance the ETT with gentle pressure along the nasal floor to pass it through the nasal cavity (**Figure 29-4B**).

FIGURE 29-3. Insertion of the nasotracheal tube. The bevel of the ETT should face the septum. **A.** Placement in the right nostril with the concave side of the ETT downward. **B.** Placement in the left nostril with the concave side of the ETT upward. When the tip of the tube enters the nasopharynx, rotate it 180°.

Slightly withdraw the ETT if any resistance is felt. Readvance the tube with a slight twisting motion to bypass the obstruction. If resistance is still met, withdraw the ETT, prepare the other nostril, and insert the tube into the other nostril.

The tip of the ETT will be past the choana and in the nasopharynx when it is inserted approximately 5 to 7 cm (**Figure 29-4B**). Continue advancing the ETT as resistance is met while it makes a 90° change of direction into the oropharynx. A slight twisting motion may be required to advance the ETT. A loss of resistance signifies that the ETT has made the curve. Several options are available if the ETT will not curve from the nasopharynx into the oropharynx. These include trying the other nostril, using an ETT 0.5 mm smaller, and reattempting intubation through the original nostril, or using an Endotrol tube (described in the next section). Stop advancing the ETT and rotate it so that its natural curve is concave upward and in the same curvature of the airway.

Advance the ETT through the oropharynx and into the laryngopharynx (**Figure 29-4C**). Listen for breath sounds through the proximal end of the ETT while advancing it. The breath sounds and air movement will be maximal when the tip of the ETT is just above the glottis. As soon as an exhalation is heard, the patient will take a breath and advance the ETT. The vocal cords are opened their widest during inspiration. This will facilitate passage of the ETT.

The patient will often cough or gag as the ETT traverses the vocal cords. Breath sounds should be audible from the proximal end of the ETT, and it should fog with each breath. The esophagus has been intubated if the patient groans or speaks. Withdraw the ETT and reinsert it during inspiration. The application of posteriorly applied pressure on the trachea (i.e., Sellick's maneuver) will occlude the esophagus and may allow easier intubation.

The ETT may be caught in the hypopharynx if resistance to the advancement of the ETT is felt. Common sites for the tip of the ETT

FIGURE 29-4. Blind nasotracheal placement. **A.** The ETT is placed within the nasal cavity. **B.** The ETT is advanced along the floor of the nasal cavity and into the nasopharynx. **C.** The ETT is advanced into the laryngopharynx. **D.** At the start of inspiration, the tube is advanced through the vocal cords and into the trachea.

to get caught are the arytenoid cartilage, piriform sinus, vallecula, and vocal cords. Withdraw the ETT 3 to 4 cm, slightly rotate the ETT clockwise or counterclockwise, and readvance it.

Inflate the ETT cuff. Confirmation of ETT placement should be assessed by auscultating both lungs while ventilating the patient with a bag-valve device through the nasotracheal tube. Adjust the position of the tube until both lungs are being ventilated equally and secure the tube (**Figure 29-4D**). Continue to ventilate the patient.

PLACEMENT WITH FIBEROPTIC ENDOSCOPY

Fiberoptic bronchoscope endoscopy, also known as fiberoptic endoscopy, is an alternative to advance the nasal ETT through the nares of choice. It decreases epistaxis, results in better navigation than the blind techniques, and results in less redirection of the ETT.¹⁴ There is no advantage between the fiberoptic bronchoscope and direct laryngoscopy in terms of the hemodynamic response to nasotracheal intubation.¹⁵

Prepare the nares and insert the ETT into the chosen nostril, as described above. Once the ETT is in the oropharynx, advance a prepared and appropriate-sized fiberoptic bronchoscope through the ETT (Chapter 28). The fiberoptic bronchoscope may be connected to oxygen or suction based on Emergency Physician preference. The view through the fiberoptic bronchoscope will reveal the epiglottis and vocal cords after exiting the nasal ETT distal opening. Consider the injection of 1% lidocaine through the fiberoptic bronchoscope side port to anesthetize the vocal cords. Advance the fiberoptic bronchoscope through the vocal cords and visualize the tracheal rings. **Gently advance the endotracheal tube over the fiberoptic bronchoscope.** Remove the fiberoptic bronchoscope. Connect the ETT to a CO₂ monitor or device and ventilator.

BLIND PLACEMENT OF THE ENDOTROL TUBE

The indications, contraindications, and patient preparation are the same as described previously. The Endotrol tube is an ETT whose tip can be controlled. It looks like a cuffed ETT but has a plastic ligature along the inner side that is connected to a ring on the proximal end of the ETT (**Figure 29-5**). Pulling of the ring exerts tension on the plastic ligature, leading to an increase in the curvature of the tip of the ETT. This will project the tip anteriorly and inferiorly (**Figure 29-6**). The procedure for inserting the Endotrol tube is the same as that for inserting an ETT. Changing

FIGURE 29-5. The Endotrol ETT. The curvature can be changed by pulling on the ring to facilitate intubation.

FIGURE 29-6. Blind nasotracheal placement of an Endotrol tube. Tension exerted on the ring of the tube causes the curvature of the tube to increase (arrow).

the curvature of the tip will aid in passage of the tube from the nasopharynx to the oropharynx and from the hypopharynx into the trachea. The tip of the Endotrol tube may be exerting continuous pressure on the anterior tracheal mucosa if the ring is sitting firmly against the nares after intubation. Cut the ligature and remove the ring.

PLACEMENT UNDER DIRECT VISION

This technique begins with nasotracheal intubation followed by direct laryngoscopy. **The placement of a nasotracheal tube using direct visualization must be performed with the patient supine.** The indications and precautions are similar to those for orotracheal intubation (Chapter 18). This method should be considered in the event of an oral injury that renders an orotracheal tube a nuisance, if blind nasal intubation is unsuccessful, or if nasal fiberoptic intubation is unsuccessful.

This procedure is initially performed as previously described. Direct laryngoscopy is performed once the ETT is inserted into the hypopharynx. Use the left hand to grasp the laryngoscope and insert the blade. A video laryngoscope may also be used.¹⁶⁻²¹ Look into the patient's mouth and visualize the epiglottis, vocal cords, and ETT. Use a Magill forceps or Tylke forceps (**Figure 29-2**) with the right hand to grasp the ETT just above the cuff (**Figure 29-7**). **Never grasp the ETT cuff, as it is delicate and can easily be damaged by the forceps.** Have an assistant grasp the proximal end of the ETT and gently advance it while the Emergency Physician simultaneously guides the tip through the vocal cords (**Figures 29-2C and 29-7**). Remove the forceps and the laryngoscope. Inflate the cuff, secure the tube, and ventilate the patient. The depth of the endotracheal tube can be verified by fiberoptic bronchoscopy.

BLIND DIGITAL INTUBATION

A technique was developed that combines blind nasotracheal intubation and digital orotracheal intubation.²² This technique starts with the procedure of blind nasotracheal intubation. If not successful, insert the index and middle fingers of the nondominant hand into the patient's mouth. Slide these fingers posteriorly over the

FIGURE 29-7. Nasotracheal intubation under direct visualization.

tongue to palpate the epiglottis. Grasp the tip of the ETT between the two fingers (**Figure 29-8A**). Pull the ETT anteriorly and behind the epiglottis (**Figure 29-8A**). Use the dominant hand to advance the ETT further into the patient's nose, advancing the tip into the trachea (**Figure 29-8B**).

FIGURE 29-8. Digital nasotracheal intubation. **A.** The ETT is grasped with the fingertips and pulled anteriorly (arrow) behind the epiglottis. **B.** The ETT is advanced into the trachea.

PEDIATRIC CONSIDERATIONS

Very little literature is available regarding nasotracheal intubation on children. In the past, this approach was an option for patients with epiglottitis and acute laryngotracheobronchitis.²³ The most recent data reserve nasotracheal intubation for children with congenital facial anomalies.²⁴ This technique cannot be recommended for children in the Emergency Department. Their small nostrils limit ETT size. Large adenoids may make passage of the ETT difficult and increase the risk of bleeding.²⁵ The use of an uncuffed ETT in children decreases the complications.²⁶ Consider the use of a feeding tube to guide the ETT and reduce complications.²⁷ Rotation of the ETT 90° counterclockwise during fiberoptic bronchoscope endoscopy may improve the success rate.²⁸

ALTERNATIVE TECHNIQUES

Numerous alternatives have been used to facilitate nasotracheal intubation. A nasogastric tube (Chapter 75) may facilitate nasotracheal intubation.^{29,30} The nasogastric tube is inserted first and the ETT is fed over the nasogastric tube. The nasogastric tube goes below the inferior turbinate and decreases the rate of epistaxis. The ETT alone usually passes between the middle and superior turbinates, causing epistaxis and turbinate trauma. Other equipment placed in the nares to form a conduit for the ETT include a bougie, red rubber catheter, and suction catheter.³¹⁻³³ **Use caution with these devices and only use them to get the ETT into the oropharynx. Advancement of these devices into the lung can result in perforation.** A video laryngoscope may be used instead of the direct laryngoscope.^{14,16-19,21,34} Video laryngoscopy is quicker than using the fiberoptic bronchoscope.³⁴

ASSESSMENT

The position of the ETT should be confirmed by end-tidal CO₂ monitoring, fogging in the ETT for at least six ventilations, loss of voice, auscultation over the chest and the epigastrium, and a chest

radiograph. Please refer to Chapter 19 for a more detailed discussion regarding confirmation of endotracheal intubation.

AFTERCARE

The ongoing care of the patient should proceed as with any other intubation technique.

COMPLICATIONS

The immediate complications of nasotracheal intubation include epistaxis, laryngeal and tracheal trauma, mucosal avulsion, retropharyngeal laceration, turbinate avulsion, intracranial placement, bacteremia, esophageal intubation, and prolonged attempts to place the tube.^{9,14,25,32,35-41} Many of these can be prevented by choosing the appropriate size ETT, ensuring adequate nasal mucosal vasoconstriction, and applying a liberal amount of lubricant to the ETT.²⁹ Risk factors for epistaxis should be assessed in every patient prior to nasotracheal intubation.⁴² Long-term complications include maxillary sinusitis, retropharyngeal abscesses, mediastinitis, nasal mucosal necrosis, and cellulitis.^{9,39,41}

SUMMARY

Nasotracheal intubation is an alternative to orotracheal intubation to secure an airway in the spontaneously breathing patient. It allows for the awake intubation while the patient maintains protective airway reflexes. Nasotracheal intubation avoids the risks of paralytic agents. It is a fairly simple procedure that should be considered in patients in whom an oral airway is considered difficult and in those with an anticipated short intubation period.

Retrograde Guidewire Intubation

Ned F. Nasr, Anna Tzonkov, and Gennadiy G. Voronov

INTRODUCTION

Oral endotracheal intubation via direct laryngoscopy or video-assisted laryngoscopy remains the “gold standard” of airway management. Difficult situations arise in which oral endotracheal intubation is impossible, is contraindicated, or fails. **Retrograde guidewire intubation is an alternative airway management technique.** The American Society of Anesthesiology difficult airway algorithm describes retrograde intubation as an alternative airway in the nonemergent pathway when mask ventilation is adequate but multiple intubation attempts are not successful. The technique should be familiar to those involved with emergency airway management.^{1,2}

Retrograde intubation was first described in 1960 by Butler and Carillo as a way to remove a tracheostomy tube in neck surgery.³ In 1963, Waters described insertion of an epidural catheter through a cricothyroid puncture as an alternative means of establishing an airway.⁴ Powell and Odzil reported a series of patients in whom retrograde intubation was employed without complications using a plastic catheter rather than an epidural catheter as a guide.⁵ The current technique of retrograde intubation varies little from these original descriptions.

Retrograde intubation represents one of several alternative maneuvers for securing the difficult airway. The technique can be used in awake, sedated, or obtunded patients who have either an anticipated or unanticipated difficult airway.⁶ The technique can be performed despite presence of secretions or blood in the oropharynx. Retrograde intubation has proven to be an effective method used by Emergency Physicians to establish a definitive airway.

The success rate of retrograde intubation is variable.⁷ Completion times for retrograde intubation vary based on physician experience. The mean length of time to intubation was 71 ± 4 seconds among health care professionals who had no prior experience with the technique but who had just completed a mannequin-aided training course.⁸ The completion of retrograde intubation within 150 seconds with a mean intubation time of 56 ± 6 seconds was seen in resident physicians after a brief instruction course.⁹

INDICATIONS

The American Society of Anesthesiologists defines a difficult airway “as the clinical situation in which a conventionally trained anesthesiologist experiences difficulty with mask ventilation, difficulty with tracheal intubation, or both.”¹¹ **Consider performing retrograde intubation in any patient in whom endotracheal intubation may be difficult, is contraindicated, or has failed.**¹⁰⁻¹⁶ **The technique can be used in awake, sedated, or obtunded patients who have either an anticipated or unanticipated difficult airway.**⁶ It is potentially indicated when airway control is required and less invasive methods have failed. Maxillofacial trauma and cervical spine fractures represent the most common etiologies of a difficult airway.¹⁷ Retrograde intubation was successful on the first attempt in these patients. Ankylosing spondylitis, rheumatoid arthritis, trismus, and congenital anomalies represent another group of challenging airway situations where retrograde intubation could be considered. It is also useful when bleeding obstructs visualization of the glottis or as an alternative in situations where a flexible fiberoptic scope is not available.^{6,18}

Another clinically important situation arises when a patient presents with impending ventilatory failure. While retrograde intubation is generally a longer procedure than orotracheal intubation, oxygenation and ventilation can be maintained with a bag-valve-mask device during the procedure.

A less common indication includes retrograde intubation of a difficult airway in a patient ventilated with a laryngeal mask airway or an intubating laryngeal mask airway.^{19,20} This indication exists because withdrawal of the laryngeal mask airway over a blindly placed catheter can result in dislodgement of the catheter, necessitating replacement of the laryngeal mask airway.²¹

CONTRAINDICATIONS

The major contraindication to retrograde intubation is the ability to control the airway with less invasive techniques. Other contraindications include an anterior neck mass overlying the cricothyroid membrane, local infection over the skin covering the cricothyroid membrane, coagulopathy, and tracheal stenosis. Apneic patients who cannot be ventilated with a bag-valve-mask device should receive a cricothyroidotomy and not a retrograde guidewire intubation. Those unfamiliar with the equipment and/or technique should not attempt this procedure. Familiarity with the procedure is required for optimum patient management.^{8,22}

EQUIPMENT

- 68 to 80 cm spring guidewire with a J-tip
- 16 to 18 gauge catheter-over-the-needle (i.e., angiocatheter)
- Endotracheal tubes, various sizes
- Sterile saline
- 10 and 20 mL syringes
- 18 gauge needles
- Hemostats
- Magill forceps or Boedeker forceps
- Sterile drapes
- Povidone iodine or chlorhexidine solution
- Face mask
- Bag-valve device
- Oxygen source and tubing
- Suction source and tubing
- Yankauer suction catheter
- 1% lidocaine
- 4% viscous lidocaine (optional)
- Topical anesthetic (e.g., lidocaine or benzocaine)
- Tape or a commercially available endotracheal tube holder

Retrograde guidewire intubation can be performed using a standard commercial retrograde intubation kit (Cook Retrograde Intubation Set; Cook Medical, Bloomington, IN). It consists of an 18 gauge needle set, 68 to 80 cm spring guidewire, an 11 French introducer catheter, a hemostat, and respiratory adapters (**Figure 30-1**). The remainder of the materials must be supplied.

PATIENT PREPARATION

The success of retrograde intubation in a patient who is awake depends on the patient's collaboration. If time permits and the patient is aware of pain, anesthetize the airway. Bilateral superior laryngeal nerve blocks and a transtracheal block would provide

FIGURE 30-1. The retrograde guidewire intubation kit. (Courtesy of Cook Medical.)

anesthesia for the airway below the epiglottis.²¹ Clean the patient's neck of any dirt and debris. Identify, by palpation, the hyoid bone, thyroid cartilage, cricoid cartilage, and cricothyroid membrane. Apply povidone iodine to the patient's neck followed by sterile drapes.

Anesthetize the patient's airway. A superior laryngeal nerve block is performed by locating the greater horn of the hyoid bone. Insert a 25 gauge spinal needle attached to a 10 mL syringe filled with 2% lidocaine until the anterior horn of the hyoid bone is contacted. Walk the needle off the anterior horn of the hyoid bone and toward the thyrohyoid membrane. Advance the needle 1 to 2 cm. Aspirate to ensure the tip of the needle is not within a blood vessel. Inject 2 mL of 2% lidocaine. Nebulized viscous lidocaine is an alternative that will anesthetize the airway in 15 to 20 minutes if there is time.¹⁷ A transtracheal block is performed by locating and penetrating the cricothyroid membrane with a 20 gauge needle and injecting 2 to 4 mL of 4% lidocaine. This will elicit a vigorous cough, which will spread the lidocaine, anesthetize the trachea, and anesthetize the vocal cords. Lidocaine or benzocaine may be sprayed into the pharynx as topical anesthesia. These blocks may allow the patient to tolerate the procedure better, depress the swallowing reflex, and lead to aspiration.²

Prepare the equipment. Place the 16 or 18 gauge catheter-over-the-needle onto a 10 mL syringe containing 3 to 5 mL of sterile saline. Select an appropriate size endotracheal tube for the patient. Check the integrity of the cuff. Lubricate the inside and outside of the distal tip of the endotracheal tube liberally. Open the retrograde guidewire kit and/or assemble all equipment. The equipment should be preassembled, prepackaged, sterilized, and stored in an easily accessible site.

TECHNIQUE

The procedure is relatively simple in theory but difficult to perform "in the heat of battle."^{8,9,23-25} Position the patient. **The ideal patient position is supine with their neck in extension.** An alternative is the sitting position or with the neck in a neutral position. Ultrasound guidance may be used if anatomic landmarks are difficult to identify.¹⁸ Stabilize the patient's larynx with the thumb and middle finger of the nondominant hand (**Figure 30-2**). Identify the cricothyroid membrane with the index finger of the nondominant hand. Leave the index finger on the cricothyroid membrane.

Insert the catheter-over-the-needle guided along the index finger, at a 20° to 30° angle upward, and through the cricothyroid

membrane (**Figure 30-2A**).²⁶ Some physicians prefer to use the needle without the catheter even though this is not recommended. The sharp needle within the trachea can cause significant injury when compared to the soft catheter and can shear off the guidewire. **Care should be taken to puncture the cricothyroid membrane just above the cricoid cartilage to avoid injury to the cricothyroid arteries.** The loss of resistance signifies that the needle is in the trachea. **Aspirate air through the saline-filled syringe to confirm correct needle placement (Figure 30-2A).** Advance the catheter until the hub is against the skin. Remove the needle and syringe while leaving the catheter pointed upward and through the cricothyroid membrane. If this has not already been done and the patient is awake, inject 2 mL of 2% to 4% lidocaine through the catheter to anesthetize the airway.

Advance the guidewire through the catheter and into the oropharynx (**Figures 30-2B and 30-3**). The guidewire may exit the mouth or nose. The preferred site of exit is the mouth, but the nose is acceptable. Insert the laryngoscope if the guidewire is not visualized and look for the guidewire. It is often in the oropharynx or hypopharynx. Retrieve it with a Magill or Boedeker forceps. Continue to advance the guidewire through the mouth (or nose) until only 4 to 5 cm of the wire is protruding from the patient's neck. **Carefully remove the catheter while firmly holding the guidewire in place. Place a hemostat on the guidewire where it enters the skin of the neck (Figure 30-2C). This will ensure that the guidewire does not pull through the skin and into the trachea.**

Select the introducer catheter if a retrograde guidewire kit is being used. Pass the introducer catheter over the guidewire that is exiting the mouth (or nose). Advance the catheter until resistance is met. This signifies that the tip of the introducer catheter is at the inside of the cricothyroid membrane (**Figure 30-2C**). Advance the well-lubricated endotracheal tube over the introducer and guidewire (**Figure 30-2D**). Continue to advance the endotracheal tube until resistance is met. The tip of the endotracheal tube should be at the inside of the cricothyroid membrane (**Figure 30-2D**). While securely holding the endotracheal tube at the patient's mouth, remove the hemostat from the guidewire. Pull on the proximal end of the guidewire until the distal tip is through the skin and just into the endotracheal tube. **Simultaneously withdraw the guidewire and introducer catheter while advancing the endotracheal tube into the trachea (Figure 30-2E).** Inflate the endotracheal tube cuff and confirm proper placement (e.g., auscultation, detection of end-tidal CO₂, and fogging in the endotracheal tube).

A second method can be used to insert the endotracheal tube. This follows the same technique described above to the point of the guidewire exiting the mouth (or nose), the guidewire being secured with a hemostat at the neck, and passing the introducer catheter over the guidewire. Remove the hemostat from the guidewire. **While securely holding the introducer catheter at the patient's mouth (or nose), remove the guidewire through the mouth (or nose).** Advance the introducer catheter an additional 2 to 3 cm into the trachea. Lubricate the endotracheal tube liberally. Place the endotracheal tube over the introducer catheter. Hold the introducer catheter securely and advance the endotracheal tube into the patient's trachea. Remove the introducer catheter. Inflate the endotracheal tube cuff and confirm proper placement (e.g., auscultation, detection of end-tidal CO₂, fogging in the endotracheal tube).

ALTERNATIVE TECHNIQUES

This technique may be performed without a formal retrograde intubation kit because the introducer catheter is not required.^{8,17,24} This follows the same technique described above to the point of

FIGURE 30-2. Retrograde guidewire intubation. **A.** A syringe containing saline is attached to the catheter-over-the-needle. The catheter-over-the-needle is inserted through the cricothyroid membrane at a 20° to 30° angle. The air bubbles in the syringe indicate air aspirated from the trachea. For clarity, the physician's hand and fingers stabilizing the airway and identifying the cricothyroid membrane are not seen in this illustration. **B.** The needle and syringe have been removed and the catheter remains. The guidewire is fed through the catheter and out the patient's mouth. **C.** The distal guidewire is clamped with a hemostat as it exits the skin of the neck. The introducer catheter has been fed over the guidewire and advanced to the cricothyroid membrane. **D.** An endotracheal tube is advanced over the guidewire and introducer catheter until its tip is at the cricothyroid membrane. **E.** The hemostat has been removed and the endotracheal tube is advanced as the guidewire and introducer catheter are removed.

the guidewire exiting the mouth (or nose) and being secured with a hemostat at the neck (**Figure 30-2C**). Lubricate the endotracheal tube liberally. Insert the guidewire through the Murphy eye and into the endotracheal tube (**Figure 30-4**). This allows the distal tip of the endotracheal tube to project approximately 1 cm distal to the site at which the guidewire enters the larynx. Some physicians prefer to load the guidewire through the tip of the endotracheal tube as an alternative. **Always hold the proximal end of the guidewire to maintain control during the procedure.**

Advance the endotracheal tube over the guidewire until resistance is felt. The tip of the endotracheal tube should be at the inside of the cricothyroid membrane (**Figure 30-4**). **Hold the proximal end of the guidewire firmly.** Release the hemostat over the neck. Pull the guidewire through the skin and just into the

endotracheal tube. Advance the endotracheal tube until it is at 20 to 21 cm at the teeth for an adult female or 22 to 23 cm at the teeth for an adult male. Hold the endotracheal tube securely at the patient's lips. Withdraw the guidewire through the endotracheal tube. Inflate the endotracheal tube cuff and confirm proper placement (e.g., auscultation, detection of end-tidal CO₂, and fogging in the endotracheal tube).

When the endotracheal tube is advanced over the guidewire until resistance is met, the tip should be situated against the inside of the cricothyroid membrane. **It is imperative to determine if the tip of the tube is in the trachea or caught on the epiglottis, arytenoid cartilage, pyriform recess, vallecula, or vocal cords.** Withdraw the endotracheal tube 2 cm if concern exists as to the position of the tip, rotate it 90°, and readvance it into the trachea. A laryngoscope or

FIGURE 30-3. The guidewire is inserted through the catheter until it exits the mouth.

fiberoptic bronchoscope can be inserted to help visualize the placement of the endotracheal tube.

Another variation involves the use of the guidewire sheath as an introducer catheter.^{24,25} Shorten the sheath by 3 to 5 cm using sterile scissors. The remainder of the technique is the same as described above. The only drawback to this technique is that the curvature of the sheath must be straightened before use to allow easy threading over the guidewire.

A central venous catheter or nasogastric tube can be used rather than a guidewire.^{17,27,28} It allows the physician to inject air through the catheter in retrograde fashion to help locate the catheter in the mouth of the severely injured patient with significant intraoral blood or secretions. This technique requires a relatively long central venous catheter. It does allow retrograde intubation without the use of a formal retrograde intubation kit.

Another version uses a lighted stylet attached to the endotracheal tube.²⁹ The lighted stylet acts as a guide to indicate the tube's location. When the tip of the endotracheal tube enters the glottic opening, a bright glow is readily seen in the anterior neck below the thyroid prominence. This glow acts as an indicator of correct endotracheal tube placement.

FIGURE 30-4. The endotracheal tube is advanced over the guidewire until the tip is against the cricoid membrane.

There are two possibilities when continuous oxygenation is required throughout the procedure.¹² A T-adaptor can be connected to the needle hub with its side arm for oxygen insufflation. A swivel adapter with a fiberoptic bronchoscopic cap can be interposed between the endotracheal tube and the bag-valve device or anesthesia breathing circuit.

ASSESSMENT

Auscultation of both lungs will confirm proper placement of the endotracheal tube and minimize the risk of intubation into the right mainstem bronchus. End-tidal CO₂ has also become part of the post-intubation routine. A chest radiograph will confirm the placement of the endotracheal tube tip in relation to the clavicles and carina. Please refer to Chapter 19 for a more complete discussion of the methods to confirm endotracheal intubation.

AFTERCARE

The patient should receive standard wound care and dressing of the skin at the neck entrance site. Wound checks and infection monitoring should continue as with any other surgical procedure. The risk of skin, tracheal, or pharyngeal infection is minimal if sterile technique is followed. Evaluate the wound and treat with appropriate antibiotics if an infection develops.

COMPLICATIONS

While complications may occur in association with retrograde intubation, the rate of complications is relatively low. Complications of retrograde guidewire intubation include those of standard endotracheal intubation. Complications can occur when the needle traverses the cricothyroid membrane.²³ **Hypoxia due to prolonged intubation time or incorrect endotracheal tube placement remains an important complication.** Drug reactions or side effects secondary to administered medications must always be considered.

Retrograde intubation is associated with additional complications related to the use of the guidewire. One case report discusses a patient with a past history of retrograde intubation who experienced a foreign-body sensation and bloody sputum 2 years after the procedure.³⁰ The patient was found to have a 10 cm segment of guidewire fixed in the soft tissue of the puncture site and extending cephalad 2 cm past the true vocal cords. The skin puncture can occur below the cricothyroid membrane. Injuries can occur to the thyroid or cricoid cartilage, the posterior wall of the larynx, the epiglottis, or the soft palate. The clinical importance of these injuries other than being a source of pain is unclear.

Three technical complications from retrograde guidewire intubation have been identified.^{23,24} Difficulties inserting the guidewire can be prevented by first aspirating air into a saline-filled syringe to confirm the proper intratracheal needle tip position. Endotracheal intubation over a flexible guidewire necessitates keeping the guidewire taut to minimize the risk of kinking. This moves the guidewire anteriorly toward the narrowest portion of the glottis and may prevent passage of the endotracheal tube as the tip can become caught on the epiglottis or the vocal cords. This problem is obviated by the use of the introducer catheter in the retrograde guidewire intubation kit. The tip of the endotracheal tube may flip out of the larynx when the introducer is being removed. The distance between the vocal cords and the point where the introducer enters and anchors the larynx averages only 1.0 to 1.3 cm in adults. The guidewire can be fed caudally into the trachea due to improper angling of the needle. The use of ultrasound visualization can help to locate the needle and guidewire in the tracheal lumen and possibly aid in the successful performance of the procedure while avoiding complications.^{18,22}

SUMMARY

Retrograde guidewire intubation requires little operator experience and minimal equipment and has a high level of skill retention.³¹ Multiple reports suggest that this technique is safe, relatively easy to learn, and routinely successful. All Emergency Physicians involved in the airway management of critically ill and injured patients should be aware of this technique as a potential method to overcome the challenge of a difficult airway. Retrograde guidewire intubation should be given due consideration in any situation in which orotracheal intubation is impossible or contraindicated.

Numerous difficult airway management devices and adjuncts have been invented and marketed. The various video-assisted laryngoscopy devices have come to dominate the realm of alternative airway management techniques. The role of retrograde guidewire intubation as a difficult airway management approach has further diminished as a consequence. However, retrograde guidewire intubation remains an easy-to-learn and potentially lifesaving tool in the Emergency Physician's airway management armamentarium.

Percutaneous Transtracheal Jet Ventilation

Gennadiy Voronov, Tamer Elattary, and Ned Nasr

INTRODUCTION

Percutaneous transtracheal jet ventilation (PTTJV) provides emergency ventilatory support in patients who cannot be adequately ventilated with a bag-valve-mask device using oral or nasal airways, a laryngeal mask airway (LMA), or endotracheal tube.¹⁻³ This includes patients with upper airway foreign bodies, upper airway neoplasms, maxillofacial trauma, laryngeal edema, or infection.^{2,4} It is used electively with general anesthesia for surgery involving the larynx and subglottic areas.⁵ PTTJV involves inserting a catheter-over-the-needle (i.e., angiocatheter) through the cricothyroid membrane and delivering oxygen to the lungs using a high-pressure oxygen delivery system.⁶

ANATOMY AND PATHOPHYSIOLOGY

Early studies of transtracheal ventilation used transtracheal catheters connected to 4 to 5 L/min of oxygen.⁷ Oxygenation with this apparatus was adequate, but patients quickly developed hypercarbia due to lack of ventilation.⁸ This "apneic oxygenation" also occurs in ventilation through a catheter attached to a bag-valve device.⁹ The low pressure and flow of oxygen generated by the bag-valve device results in increases in PaCO₂ of 4 mmHg/min and the rapid development of respiratory acidosis.^{1,10} Numerous studies have since demonstrated that intermittent jets of pressurized 100% oxygen at 50 pounds per square inch (psi) allow for both oxygenation and adequate ventilation.^{10,11}

The anterior neck provides direct access to the airway via the trachea as it extends from the larynx into the lungs (**Figure 31-1**). At the top of the laryngeal skeleton is the thyroid cartilage. It lies at the level of the fourth and fifth cervical vertebrae. The laryngeal prominence (i.e., Adam's apple) of the thyroid cartilage is more prominent in men and is easily palpated. The cricoid cartilage lies just inferior to the thyroid cartilage at the level of the sixth cervical vertebra. It serves as the junction of the larynx and trachea. Multiple cartilaginous rings support the trachea. Between the cricoid and thyroid cartilages lies the cricothyroid membrane.

FIGURE 31-1. Airway structures of the neck.

The cricothyroid membrane is a palpable membranous depression just inferior to the laryngeal prominence and is the access site for PTTJV.¹² The cricothyroid artery is a branch of the superior thyroid artery. It travels transversely across the cricothyroid membrane just below the thyroid cartilage. Placement of the catheter through the lower half of the cricothyroid membrane will prevent injury to this small artery.¹³

The Emergency Physician should attempt to insert the largest possible catheter based on the limited information obtained from palpation of the landmarks. The cricothyroid membrane is found at different distances from the skin that vary based on patient weight and neck circumference. The mean of depth distance is approximately 2.3 mm.¹⁴ Ultrasonography can be used to identify the landmarks if unable to palpate the cricothyroid membrane.¹⁴⁻¹⁶ It is usually more difficult to identify the cricothyroid membrane in adult females compared to adult males irrespective of body weight.¹⁶

Oxygen is delivered via bulk flow through the cannula into the trachea and lungs. Entrainment of room air translaryngeally via the Venturi principle is negligible, even with minimal upper airway obstructions.¹ Near 100% O₂ is delivered with each insufflation.

Inhalation occurs through the catheter via a pressurized flow of oxygen. Exhalation occurs passively through the elastic recoil of the lungs and chest wall.³ The minute ventilation delivered during PTTJV is proportional to the volume of air injected, the driving air pressure, and the degree of upper airway obstruction.^{2,17} Animal studies demonstrate that PTTJV delivers more tidal volume than positive-pressure mask ventilation with the same tracheal and transpulmonary pressures despite delivery of oxygen from a pressurized source.²

INDICATIONS

PTTJV is indicated as a backup emergent airway in any patient who cannot be endotracheally intubated or ventilated with a bag-valve device despite the use of a jaw-thrust maneuver, oropharyngeal airway, nasopharyngeal airway, or LMA.^{1,2,8} It serves as a simple, relatively safe, and effective alternative to cricothyroidotomy.^{1,7} It can be performed at any age. PTTJV is preferable to a surgical cricothyroidotomy in infants and children up to 10 to 12 years old due to it being easier to perform and its potentially fewer complications.¹⁸

PTTJV is the procedure of choice in the pediatric age group for establishing an emergent airway when endotracheal intubation fails.⁹ PTTJV can serve as a quick alternative to a difficult intubation. It is especially valuable in cases of maxillofacial trauma, suspected cervical spine injury, or when nasal intubation is contraindicated or unsuccessful.^{7,8,19} PTTJV is occasionally performed by the Anesthesiologist as a method of airway management when a difficult intubation is anticipated.²⁰

This procedure is indicated in cases of partial upper airway obstruction due to foreign bodies, laryngeal edema, neoplasm, or infection.^{2,4} PTTJV serves as an emergent airway in cases of upper airway foreign bodies and can assist in dislodging the foreign body.^{7,9} Animal studies have demonstrated that the expulsion of foreign bodies from the hypopharynx and upper trachea is possible with high-frequency jet ventilation, an effect similar to the Heimlich maneuver.¹⁹ Approximately 30% of the air flow from transtracheal jet ventilation is directed cephalad and can therefore assist in the expulsion of airway foreign bodies.²¹

PTTJV has numerous advantages when compared to an emergent cricothyroidotomy.^{1-12,17,19,21-28} It is easier and faster to perform. The technique is simpler to learn. The need for many instruments, surgical preparation and technique, and an assistant is eliminated. The complications of bleeding, glottic stenosis, subglottic stenosis, and tracheal erosion are significantly lessened. PTTJV causes less cosmetic disfigurement. PTTJV can also direct secretions and foreign bodies out of the proximal trachea.

CONTRAINDICATIONS

PTTJV is contraindicated in patients who can be orally or nasally intubated. Anterior neck trauma may be a contraindication to PTTJV. Damage to the larynx or cricoid cartilage is a contraindication to PTTJV. Catheter placement may result in laryngeal disruption if there is laryngeal trauma.^{8,17} It should not be performed in patients with partial or complete transection of the trachea. Lower tracheal or proximal bronchial tree disruption can result in an increased risk of pneumothorax and pneumomediastinum with high-pressure ventilation.^{8,9,17}

Complete airway obstruction is an absolute contraindication to PTTJV.^{8,10,17} Exhalation requires passive recoil of the lungs and chest wall and a patent airway for outflow of gas. A patient with a complete upper airway obstruction is at an increased risk for barotrauma (e.g., pneumothorax and pneumomediastinum). Numerous studies have been performed to evaluate PTTJV with varying degrees of upper airway obstruction. Progressively increasing airway obstructions up to 80% did not cause barotrauma.²⁷ **Less air escapes and more volume is forced into the lungs with upper airway obstruction.** The tidal volume increases with increasing airway obstruction. Once a patient develops complete upper airway obstruction, auto-PEEP (i.e., end-expiratory alveolar pressure above the set level of positive end-expiratory pressure [PEEP]) will develop as air is trapped within the thoracic cavity with no outlet and insufflation of air under pressure continues. This will ultimately result in barotrauma and decreased mean arterial pressure.²⁶

EQUIPMENT

- Pressurized oxygen source, wall source or tank at 50 psi
- Povidone iodine or chlorhexidine solution
- Commercially available PTTJV kit or a self-assembled kit from available components
- 12 to 16 gauge, 2 to 3 inch catheter-over-the-needle (i.e., angiocatheter)

- Noncompressible high-pressure oxygen tubing
- Valve device (manual push valve, Y connector, T piece)
- 10 mL syringe
- Sterile saline
- Sterile drapes
- Local anesthetic solution (e.g., 1% lidocaine)
- 3–0 nylon suture
- Needle driver
- Bag-valve device
- 3 mL syringe
- Adult endotracheal tube connector

A PTTJV system can be purchased from a commercial company (Table 31-1). It may also be assembled with individual parts.¹ Other alternative catheters include vessel dilators from central venous kits (5 to 7 French for younger children and 7 to 9 French for adults), a catheter introducer, or large angiocatheter.²⁹ Examples of PTTJV systems are shown in Figures 31-2 through 31-8. The components of a PTTJV system are quite simple (Figure 31-9). The oxygen source may be a wall supply or tank. It should have a pressure regulator that can provide 100% O₂ at 50 psi through noncompressible high-pressure tubing. Along the tubing, there must be a valve (e.g., Y connector or manual push valve) to allow intermittent flow of oxygen.⁸ The flow into the trachea is regulated by manual control of this valve. Ventilations should be delivered at a rate of 12 to 20 breaths per minute. Oxygen flow rates will vary with catheter size. Flow rates for 20, 16, and 14 gauge catheters at 50 psi are 400, 500,

TABLE 31-1 Some of the Commercially Available Devices		
Name	Manufacturer	Comments
AincA Manual Jet Ventilator	Anesthesia Associates	Reusable Thumb depression mechanism gives oxygen flow Connects to luer lock female connection For adults, children, and infants Adapters to directly connect to endotracheal tube or fiberoptic bronchoscope
AincA MRI Conditional 3.0 Tesla Manual Jet Ventilator	Anesthesia Associates	Reusable Similar to AincA Manual Jet Ventilator Magnetic resonance imaging compatible for ≤ 3 Tesla strength
Enk Oxygen Flow Modulator Set	Cook Medical	Disposable single-use Packaged as complete set 7.5 cm length catheter, 2.0 mm inner diameter
Manual Jet Ventilator	Instrumentation Industries	For use when jet ventilator is not available Disposable single-use outlet tube Reusable rest of system Adult (13 gauge) and children's (14 gauge) versions
Manujet III	VBM Medizintechnik	With or without adjustable pressure regulator Packaged as complete set with 13, 14, and 16 gauge catheters For adults, children, and infants with three catheters
Trans-Tracheal Catheter	Acutronic Medical System	Needle for tracheal puncture Adult (13 gauge) and children's (14 gauge) versions
Ventrain	Ventnova Medical	Available device or kit Uses suction to remove gases during expiration

and 1600 mL/s, respectively.¹¹ The inspiratory time is brief compared to the expiratory time by a ratio of 1:2 to 1:9 seconds.^{2,3,22}

The patient may be temporarily oxygenated through a transtracheally placed catheter if a high-pressure system is unavailable.³⁰ Attach a 3 mL syringe without the plunger to the 12 to 16 gauge catheter of a catheter-over-the-needle (i.e., angiocatheter). Insert a standard endotracheal tube connector from a size 5 to 9 mm inner diameter endotracheal tube into the barrel of the syringe. Connect the bag-valve device to the connector and begin ventilation while preparing for more definitive airway control.^{7,9,31,32}

The commercially available PTTJV kits are designed to provide 100% oxygen at 50 psi, which has been shown to provide both adequate oxygenation and ventilation.^{10,11} Several recent studies have compared the effectiveness of a self-made apparatus with the commercial kits. They have shown that flow rates of > 15 L/min with the regulator wide open are needed to produce equivalent flow rates.³³ Using flow rates less than 15 L/min will result in failure

FIGURE 31-9. The components of high-pressure jet ventilation systems. **A.** Modified from Mittal and Baren.²⁸ **B.** Modified from Patel.³

of ventilation within 60 seconds. **A surgical cricothyroidotomy should be performed if a high-pressure system is unavailable and a more definitive airway cannot be obtained.**³⁴

PATIENT PREPARATION

The establishment of PTTJV requires not only proper insertion of the transtracheal catheter but also proper setup of the ventilatory equipment. The required equipment should be prepackaged and placed where it is readily accessible. Ensure that the fittings are secure and the tubing is not damaged. Place the patient supine and in the sniffing position if not contraindicated. The patient is most likely already in the proper position, as this technique is most often performed on apneic patients in whom other intubation techniques have failed. Place a rolled towel behind the middle of the neck to hyperextend the neck and allow for better access. Identify by palpation the hyoid bone, thyroid cartilage, cricoid cartilage, and cricothyroid membrane. Clean the anterior neck of any dirt and debris. Apply povidone iodine or chlorhexidine solution to the anterior neck and let it dry if there is time. Prepare the needed equipment. Attach a 12 to 16 gauge catheter-over-the-needle (i.e., angiocatheter) to a 10 mL syringe containing 5 mL of sterile saline.

TECHNIQUE

Stand at the side of the bed and adjacent to the patient's head and neck. **Reidentify the anatomic landmarks. This is crucial to**

perform this procedure. Use the nondominant hand and place the thumb on one side of the thyroid cartilage and the middle finger on the other side. Use these fingers to stabilize the larynx. Use the index finger to identify the anatomic landmarks.^{3,8} Start at the laryngeal prominence (i.e., Adam's apple) and work inferiorly. The soft membranous defect inferior to the laryngeal prominence is the cricothyroid membrane. Below this is the firm cartilaginous ring of the cricoid cartilage.

Insert the catheter-over-the-needle (i.e., angiocatheter) through the skin, subcutaneous tissue, and inferior aspect of the cricothyroid membrane. **The inferior aspect of the cricothyroid membrane is the preferred site as it avoids injury to the cricothyroid arteries.**⁹ Direct the catheter-over-the-needle inferiorly and at a 30° to 45° angle to the upright perpendicular (**Figure 31-10A**). Maintain constant negative pressure within the syringe as it is advanced (**Figure 31-10B**). **Continue to advance the catheter-over-the-needle while maintaining negative pressure until air bubbles are visible in the syringe and a loss of resistance is felt.**^{3,8} **These signify that the tip of the angiocatheter is within the trachea.**

Once placement within the trachea is confirmed, securely hold the needle and advance the catheter until the hub is against the skin (**Figure 31-10C**). Remove the needle and syringe (**Figure 31-10C**). Reattach the syringe without the needle to the catheter. **Aspirate once again to reconfirm placement of the catheter within the trachea.** The 2 to 3 cm catheter should be long enough to pass into the tracheal lumen without sitting against the posterior wall. If the

FIGURE 31-10. Insertion of the transtracheal catheter. **A.** The catheter-over-the-needle is inserted 30° to 45° to the perpendicular (*dotted line*) and aimed inferiorly. **B.** Application of negative pressure to a saline-containing syringe during catheter insertion (*arrow*). Air bubbles in the saline confirm intratracheal placement of the catheter. **C.** The catheter is advanced until the hub is against the skin. The needle and syringe are then removed. **D.** High-pressure oxygen tubing is attached to the catheter and ventilation is begun.

catheter tip directly touches or faces the posterior tracheal wall, there is the risk of forcing air submucosally.¹⁷ **Firmly grasp and hold the catheter hub at the skin of the neck.** Remove the syringe. Attach the oxygen tubing to the catheter (**Figure 31-10D**). Begin ventilation and continue until a more permanent and secure airway is established.⁸ **Watch for adequate chest rise with ventilation and allow for complete elastic recoil of the chest wall before giving the next breath to avoid air trapping and barotrauma.**

ASSESSMENT

PTTJV requires continuous cardiac and pulse oximetry monitoring to evaluate oxygenation. Continuous capnography can be used to assure adequate ventilation. Arterial blood gas samples should be

obtained periodically to look for hypoxia and hypercarbia. **Careful attention must be paid to maintaining a patent upper airway to allow for passive expiration and avoid barotrauma.** An oropharyngeal airway, nasopharyngeal airway, or a jaw-thrust maneuver is often adequate.

The catheter, oxygen tubing, and patient must be continually assessed during PTTJV. Check the catheter tubing at regular intervals for signs of dislodgement or kinking. Examine the patient for crepitus in the neck and torso. The catheter tip is most likely directly against or directed toward the mucosa of the posterior tracheal wall if there is crepitus. Oxygen is being forced into the submucosal tissues and tracking subcutaneously. Remove the catheter and reinsert a new one. Obtain a chest radiograph to assess the patient for a pneumomediastinum, pneumopericardium, or pneumothorax that

may require decompression. **Continuously monitor pulse oximetry, cardiac monitoring, and capnography.**

AFTERCARE

The catheter and tubing must be secured to prevent accidental dislodgement.³ One person must continuously hold the hub of the catheter against the patient's skin during PTTJV while a second person secures it. There are three ways to secure the equipment. The first and preferred method is to suture it in place. Place a skin wheal of local anesthetic solution (e.g., 1% lidocaine) next to the catheter hub. Use 3–0 nylon suture to place a stitch through the skin wheal and tie it securely. Do not cut the suture. Wrap the long end of the suture around the catheter hub two or three times and tie it securely to the tail of the suture. Wrap the long end of the suture around the oxygen tubing, just above the attachment to the catheter hub, two or three times and tie it securely to the tail of the suture. Alternatively, wrap a piece of umbilical or plain tape around the patient's neck, the catheter hub, and the oxygen tubing. A second alternative is to attach a commercially available endotracheal tube holder around the patient's neck and connect it to the oxygen tubing. The catheter will still have to be secured with a suture or by being taped to the oxygen tubing and skin.

The patient should be reevaluated for possible endotracheal intubation. Studies have shown that subsequent attempts have been successful. It is possible that the positive pressure used in PTTJV increases the success rate.³

COMPLICATIONS

PTTJV is a relatively safe and effective means of establishing an emergent airway in a patient who cannot be intubated or ventilated by another mechanism. Complications are fewer than with a cricothyroidotomy, but they do occur and must be anticipated.

Subcutaneous emphysema occurs most commonly when the transtracheal catheter is misplaced, becomes dislodged into the soft tissues of the neck during ventilation, or is placed against the mucosa of the posterior tracheal wall.^{1,7,8} It may also occur if catheter placement is unsuccessful on the first attempt, creating a port for leakage of pressurized air into the subcutaneous tissues of the neck.⁸ Frequent examination of the catheter site for evidence of subcutaneous emphysema may provide the earliest clue to catheter malfunction.

Barotrauma may present as a pneumothorax, pneumomediastinum, or pneumopericardium. It may be a result of upper airway obstruction. The exhalation of air is passive and depends on a patent upper airway. **It is important to monitor chest rise and fall as evidence of continued air exchange.**¹ An oropharyngeal airway, nasopharyngeal airway, or jaw-thrust maneuver will often provide adequate upper airway patency.⁸ **Assume that any sudden change in the patient's heart rate or blood pressure during PTTJV is secondary to a tension pneumothorax until proven otherwise.** There has been a case report of laryngospasm with PTTJV use during an elective surgical procedure.²³ It resulted in sudden desaturation and hypotension that were easily resolved with the administration of a paralytic agent.

Catheter obstruction is a potential complication. The catheter will most commonly kink as it traverses the soft tissues of the neck.^{1,8} This may occur if the catheter is dislodged or from the high-pressure ventilation. The use of a commercially available kink-resistant catheter greatly reduces this risk.

The catheter may be inappropriately placed. Misplacement of the catheter into the submucosa of the larynx can lead to a laryngeal pneumatocoele. If this is suspected or identified, remove the catheter and reinsert a new one. The pneumatocoele can be aspirated with a needle and syringe after placement of a new transtracheal catheter.⁸ Misplacement of the catheter posteriorly through the back of the

trachea and perforation of the esophagus constitute a theoretical concern that has never been reported.^{1,7,8}

Pulmonary aspiration is a potential complication of PTTJV. The epiglottis provides no airway protection. The small transtracheal catheter does not prevent aspiration of secretions or gastric contents into the lungs. Animal studies have demonstrated that pulmonary aspiration did not occur despite variable frequencies of ventilation, variable oxygen flow pressure, and cardiac compressions during cardiopulmonary resuscitation (CPR).^{24,25} The pressurized flow of air through the catheter provides an adequate forceful gas outflow from the lungs, which may prevent pulmonary aspiration.^{24,25} Secretions and foreign bodies have been shown to stay above the jetting catheter while PTTJV is in progress. **Great care must be taken to assure complete suctioning and cleansing of the upper airway above the catheter if PTTJV is to be discontinued.**²⁵

Less serious complications include local hematoma formation at the catheter insertion site, hemoptysis, and cough.^{1,7,8} The use of nonhumidified oxygen in the catheter has been reported to cause irritation and erosion of the tracheal mucosa.¹

SUMMARY

PTTJV is an effective and easy method for establishing an emergent airway in patients who cannot be ventilated with a bag-valve device or intubated. The indications for PTTJV are the same as those for a cricothyroidotomy. Placement of a catheter through the cricothyroid membrane and attached to a high-pressure oxygen source will provide adequate oxygenation and ventilation until a more definitive airway can be established. This is an airway management technique that is rapidly performed and should be considered as a reliable backup rescue technique for the "can't intubate, can't ventilate" patient.

Cricothyroidotomy

Charles Boland, Ned Nasr, and Gennadiy Voronov

INTRODUCTION

Establishment of an airway is imperative to patient survival.¹ The most predictive factor of survival from cardiac arrest is establishment of an airway.² The Emergency Physician is occasionally confronted with an airway that is extremely difficult or even impossible to obtain by endotracheal intubation.³ Up to 4% of all

emergent airways require a cricothyroidotomy.⁴⁻⁸ Up to 7% of trauma patients who present in cardiopulmonary arrest will require a cricothyroidotomy.⁶

The technique of cricothyroidotomy has been documented in use since the early 1900s. Chevalier Jackson condemned its use in 1921 because of fears of subglottic stenosis.^{9,10} Jackson's technique involved incising the cricoid cartilage, which was responsible for the resulting subglottic stenosis. The technique was popularized again in 1966 by Brantigan and Grow, but it was considered primarily an elective procedure.^{9,10} **Cricothyroidotomy has since evolved into the surgical airway of choice for emergent situations in which other intubation methods have failed or are contraindicated.**^{5,11} The Emergency Physician using rapid sequence induction to intubate patients must be knowledgeable and skilled in performing a cricothyroidotomy.⁶ The success rate of a cricothyroidotomy ranges from 96% to 100%.^{7,12}

The most difficult part of performing a cricothyroidotomy is deciding to do it. The Emergency Physician often continues to attempt intubation in hopes of gaining the airway. The decision to perform a cricothyroidotomy is often made after the patient is hypoxic and cannot be intubated, oxygenated, or ventilated. There are often multiple intubation attempts before the decision is made to perform a cricothyroidotomy. Quickly determine if intubation is unsuccessful and prevent delaying the cricothyroidotomy. Follow a difficult airway algorithm.

A cricothyroidotomy has numerous advantages over a tracheostomy.^{9,13,14} A cricothyroidotomy is easier, faster, and safer to perform. It can be performed in less than 2 minutes and performed by those with little or no surgical training. It does not require the support of an Operating Room and a large amount of equipment. The anatomic landmarks are easily palpated, easily seen, and superficial. The procedure does not require a deep dissection as the structures are located superficially. The cricothyroid membrane is not covered by any structures that would interfere with the procedure. There is a minimal chance of injuring the esophagus because the cricothyroid membrane is in the anterior part of the neck. A cricothyroidotomy can be performed with the patient's neck in a neutral position rather than the extended position. This is especially important in those with potential cervical spine injuries. The procedure has fewer associated complications than a tracheostomy. The skin incision will heal with a smaller and less noticeable scar, although this is not a concern when securing an airway emergently.

ANATOMY AND PATHOPHYSIOLOGY

The cricothyroid membrane is located between the thyroid cartilage superiorly and the cricoid cartilage inferiorly (**Figure 32-1**).¹⁵ **Identify the cricothyroid membrane by palpation of the surrounding cartilaginous structures.**¹⁶ Use the nondominant hand. Place the thumb on one side of the thyroid cartilage and the middle finger on the other side (**Figure 32-2**). Palpate the laryngeal prominence (i.e., Adam's apple) with the index finger. **It is important to locate the hyoid bone superiorly to ensure the incision is not above the vocal cords.**¹⁵ Just below the thyroid cartilage is a gap before reaching the cricoid cartilage. This soft tissue gap is the location of the cricothyroid membrane.¹⁵ Ultrasound can be used to identify the cricothyroid membrane and may be more accurate than palpation.¹⁷⁻²¹ Either perform ultrasound in advance and mark the cricothyroid membrane or use it during the procedure.

The cricothyroid membrane is a thin membrane measuring 2 to 3 cm in width and only 7.8 to 10 mm in height in the adult.^{11,14} It is located approximately 1 cm below the true vocal cords.^{14,15,22} **There is relatively little subcutaneous tissue and few to no vascular structures overlying the cricothyroid membrane.** The anterior

A

B

FIGURE 32-1. Anatomy of the airway in the neck region. **A.** Topographic anatomy. **B.** The framework of the airway.

cricothyroid arteries travel from lateral to medial over the superior border of the cricothyroid membrane. The anterior jugular veins may lie immediately superior and lateral to the cricothyroid membrane. Farther lateral and posterior are the great vessels of the neck. Posterior to the larynx and trachea is the esophagus. **It is important not to make the incision too deep and risk an esophageal intubation or injury.**

INDICATIONS

The most frequent indication for an emergent or urgent surgical airway is the inability to intubate orotracheally with less invasive techniques.³ These less invasive techniques may have failed or may be contraindicated.¹³ Attempt to orotracheally or nasotracheally intubate prior to creating a surgical airway.^{7,11} Common reasons for failed orotracheal intubation include airway hemorrhage,

FIGURE 32-2. Proper hand positioning to identify the airway structures of the neck.

cervical spine injuries, deformities of the mouth and/or pharynx, distortion of the normal anatomy, edema, laryngospasm, masseter spasm, obesity, severe facial trauma, severe neck trauma, upper airway hemorrhage, upper airway obstruction, and vomitus in the oropharynx.^{11,12,14,23,24} **It is of the utmost importance to have the surgical airway supplies nearby if a difficult airway is suspected.** The old saying “A surgical airway is better than a deceased patient with a good-looking neck” holds quite true.

Needle cricothyroidotomy is the emergent “surgical” airway of choice in a patient younger than 8 to 10 years of age.^{14,25} The cricothyroid membrane and surrounding structures are much smaller in young children and more difficult to access. It is easier to injure one of the cervical vessels or the esophagus when a standard cricothyroidotomy is performed in a child. Subglottic stenosis is a common late complication following a cricothyroidotomy in children.²⁵ A needle cricothyroidotomy is a safer alternative and allows for adequate oxygenation and ventilation until a formal tracheostomy or other method of intubation can be performed. The small caliber of the catheter does not often provide adequate oxygenation and ventilation for an adult.

CONTRAINDICATIONS

There are a few absolute contraindications to performing a cricothyroidotomy. The most important is if the patient can be intubated by less invasive methods. Partial or complete transection of the airway is a contraindication to a cricothyroidotomy. A tracheostomy is the preferred method of securing the airway in a complete airway transection. Do not perform a cricothyroidotomy with a fracture or significant injury of the cricoid cartilage, larynx, and/or thyroid cartilage.

There are some situations where the performance of a cricothyroidotomy may be less desirable. The presence of laryngeal pathology (e.g., fracture or tumor) may preclude the performance of a cricothyroidotomy and necessitate a high tracheostomy.^{14,26} There is a higher incidence of long-term complications following a cricothyroidotomy if a patient has been previously intubated for a prolonged period.²⁶ This does not prevent the performance of a cricothyroidotomy. Consider an early revision to a tracheostomy to minimize

these complications. Other relative contraindications to performing a cricothyroidotomy are the presence of a coagulopathy, hematoma of the neck, or massive neck swelling; all of which increase the risk of bleeding and distortion of the anatomy. Unfamiliarity with the technique may lead to increased complications.¹⁴

EQUIPMENT

■ GENERAL SUPPLIES

- Sterile gloves, gowns, and drapes
- Face mask and eye protection
- 1% lidocaine local anesthetic solution
- Syringes, 5 and 10 mL
- Needles, 18 to 27 gauge
- Bag-valve-mask device
- Oxygen source and tubing
- Suction source, tubing, and catheter
- Pulse oximeter
- Noninvasive blood pressure cuff
- Cardiac monitor
- End-tidal CO₂ monitor

■ SURGICAL CRICOTHYROIDOTOMY

- Povidone iodine or chlorhexidine solution
- #11 scalpel blade on a handle
- Trousseau tracheal dilator or curved 6 inch hemostat
- Tracheal hook
- Hemostats, 4 small
- Needle driver
- Suture scissors
- Tracheostomy tubes, sizes #4 and #6
- Endotracheal tubes, #5 or #6
- Tracheostomy tape (i.e., twill tape)
- 3–0 sutures for hemostasis (e.g., Dexon, Vicryl, or chromic)
- 3–0 nylon sutures for skin closure
- 1 inch tape or a commercially available endotracheal tube holder
- Gauze 4×4 squares
- Iodoform gauze ribbon
- Percutaneous cricothyroidotomy kit, adult and pediatric sizes

■ NEEDLE CRICOTHYROIDOTOMY

- Povidone iodine or chlorhexidine solution
- 14 gauge catheter-over-the-needle (angiocatheter), 2 inches long
- 5 mL syringe
- Tape
- Percutaneous transtracheal jet ventilator (Chapter 31)

The equipment should be prepackaged in a sterile tray that is readily accessible. A minimal amount of equipment is needed to perform a cricothyroidotomy (**Figure 32-3**). Some institutions maintain separate cricothyroidotomy and tracheostomy trays. Others have one tray that contains the equipment necessary to perform both procedures. A thoracotomy tray usually contains all the required equipment to perform this procedure if a cricothyroidotomy tray is not immediately available.

A

B

FIGURE 32-3. The minimal equipment to perform a cricothyroidotomy. **A.** A “homemade” kit (from top to bottom: an endotracheal tube, a hemostat, a scalpel, and a tracheal hook). Some kits contain a Trousseau dilator instead of the hemostat. **B.** The Cook Surgical Cricothyroidotomy kit (top to bottom: tracheostomy tube, Trousseau dilator, scalpel, tracheal hook, syringe, tracheal ties). (Photo courtesy of Cook Medical, Bloomington, IN.)

Should the Emergency Department stock surgical cricothyroidotomy kits, percutaneous cricothyroidotomy kits, or both? The answer to this will depend on Emergency Physician preference, hospital stores, and available budget. There are many cricothyroidotomy devices commercially available (**Table 32-1**). The Melker Universal Emergency Cricothyroidotomy Catheter Set (Cook Inc., Bloomington, IN) may resolve this issue for some Emergency Departments. This single-use, disposable kit contains all the equipment required to perform both types of cricothyroidotomies (**Figure 32-4**). The convenience of having all the required equipment readily available in one kit can clearly justify the cost. Unfortunately, this kit is only available in one adult size.

PATIENT PREPARATION

A cricothyroidotomy is most commonly an emergent procedure following unsuccessful attempts at orotracheal intubation. The patient is already unconscious, so informed consent is not possible. Informed consent must be obtained if the patient is awake prior to induction and there is high suspicion of a difficult airway.

Have the nursing staff apply and monitor the electrocardiography (ECG), end-tidal CO₂, noninvasive blood pressure cuff or arterial

TABLE 32-1 Some Commercially Available Devices

Name	Manufacturer	Comments
Arndt Emergency Cricothyrotomy Catheter Set	Cook Medical	6.0 cm length 3.0 mm inner diameter Extra stiff guidewire
Emergency Transtracheal Airway Catheter	Cook Medical	6 French size 5.0 and 7.5 cm lengths For needle cricothyroidotomy Kink resistant
Melker Emergency Cricothyrotomy Catheter Set	Cook Medical	Complete set with 3.8, 4.2, and 7.5 cm lengths Corresponds to 3.5, 4.0, and 6.0 mm inner diameter Extra stiff guidewire Uses Seldinger technique
Nu-Trach Adult Emergency Cricothyrotomy Kit	Mercury Medical	Complete set with 4.5, 6.0, and 7.2 mm inner diameter airway Uses special introducer contained in set
Patil Cricothyrotomy Emergency Catheter Kit	Cook Medical	9 French catheter
Pertrach Emergency Cricothyrotomy Kit	Pulmodyne	Available in 3.9, 4.0, 4.1, 4.4, and 6.8 cm lengths Corresponds to 3.0, 3.5, 4.0, 5.0, and 5.6 mm inner diameter Splitting needle and dilator
Pedia-Trache Emergency Cricothyrotomy Kit	Mercury Medical	Complete set with 3.0, 4.0, and 5.0 mm inner diameter airway Uses special introducer contained in set
Portex Cricothyrotomy Kit (PCK)	Portex	Soft seal cuff
Quicktrach II	VBM Medizintechnik	Available in 2.0 and 4.0 mm inner diameter Conical needle tip allows smallest stoma Removable stopper prevents perforation of tracheal back wall
Rusch Quicktrach	Teleflex	Anatomic-shaped cannula Available in 2.0 and 4.0 mm inner diameter Removable stopper prevents perforation of tracheal back wall
Cric-Key	Engineered Medical Systems	Combines functions of bougie, dilator, stylet, and trach hook Hybrid surgical technique
Cric-Knife	Engineered Medical Systems	Semirigid smooth plastic introducer and cuffed 5.2 mm tube Combines a double-edge scalpel with a sliding hook Hybrid surgical technique
Cricothyrotomy Tactical Medical Model	Chinook Medical	Contains cuffed tube 6.0 mm inner diameter
H&H Emergency Cricothyrotomy Kit	H&H Medical	Contains cuffed tube 6.0 mm inner diameter
Kwik Cric Emergency Field Cricothyrotomy Kits	Boundtree Medical	Available in sizes 5.5, 6.0, and 6.5 mm inner diameter endotracheal tube
Melker Surgical Cricothyrotomy set	Cook Medical	9.0 cm length Corresponds to 5.0 mm inner diameter
Melker Universal Emergency Cricothyrotomy Catheter Set	Cook Medical	Combines contents from percutaneous and surgical kits For percutaneous and surgical cricothyroidotomy
Rusch Easycric	Teleflex	Anatomic design Available in adult size 5 Hydrophilic coating for easy insertion Uses Seldinger technique
Surgicric	VBM Medizintechnik	Available in 6.0 mm inner diameter Available in three complete sets I: rapid four-step technique II: classic surgical technique III: Seldinger technique

line, and pulse oximetry. A fully functioning suction apparatus with a variety of catheters must be immediately available.

Place the patient supine with their head in a neutral position. Place a rolled towel under the patient's upper shoulders if no contraindications exist (**Figure 32-5**). This position offers excellent exposure through mild neck extension, stabilizes and prevents the airway structures from moving, and lengthens the cricothyroid membrane. While it is not impossible to perform a cricothyroidotomy with a cervical collar on the patient, it is very difficult. It is preferable to carefully remove the collar while an assistant maintains in-line stabilization of the head and neck in a neutral position. If the patient is at risk for a cervical spine injury, have an additional assistant maintain the airway and ventilate the patient with a bag-valve-mask device.

Prep the skin of the anterior neck with povidone iodine or chlorhexidine solution and place sterile drapes to isolate a surgical field. The Emergency Physician performing the procedure should be clad in a mask, sterile gown, and sterile gloves. **The circumstances in which the procedure is usually performed often require that the airway be obtained rapidly.** A quick spray of povidone iodine or chlorhexidine and sterile gloves will suffice in an emergency.

TECHNIQUES

One or two assistants should be maintaining the airway by ventilating the patient with a bag-valve-mask device or a supraglottic airway device while a cricothyroidotomy is performed. Stand on the

FIGURE 32-4. The Melker Universal Cricothyroidotomy Kit. (Photo courtesy of Cook Medical, Bloomington, IN.)

patient's right side if the Emergency Physician is right-handed.¹⁴ The position is reversed for the left-handed Emergency Physician.

Stabilize the large thyroid cartilage in place with the thumb and middle finger of the nondominant hand (**Figure 32-2**).^{11,27} **The immobilization of the larynx cannot be overemphasized. The procedure will fail and life-threatening injury can result if the larynx is not secure and the landmarks are lost. Identify the anatomic landmarks necessary to perform this procedure.^{16,28} This is critical to the successful performance of a cricothyroidotomy.** Place the index finger over the laryngeal prominence (i.e., Adam's apple). Move the index finger inferiorly to identify the cricothyroid membrane, cricoid cartilage, and tracheal rings in this order. Move the index finger superiorly until it falls back into the cricothyroid membrane. Leave the index finger over the cricothyroid membrane. Infiltrate the area of the incision with local anesthetic solution after the landmarks are identified if the patient is awake and stable.

TRADITIONAL TECHNIQUE

Make a 2 to 3 cm transverse incision, centered in the midline, through the skin and subcutaneous tissue (**Figures 32-6 and 32-7A**). Continue the incision through the cricothyroid membrane. All layers may be incised simultaneously with one incision as one gains skill with this procedure. The beginner should proceed with some caution because there is a small risk of incising through the

FIGURE 32-5. Patient positioning with a rolled towel under their neck and upper shoulders.

FIGURE 32-6. The cricothyroidotomy site. The dotted line represents the incision over the cricothyroid membrane.

posterior wall of the airway.^{11,14} **Make the incision no longer than 3 cm or 1.5 cm on either side of the midline, as this represents the width of the cricothyroid membrane.^{10,27} Longer incisions risk injury to the anterior jugular veins that lie just lateral to the thyroid cartilage.¹⁴**

Longitudinal incisions in the midline are not recommended. They take longer to perform and require repositioning after the skin incision. The primary indication for a longitudinal skin incision is in the patient with a suspected laryngeal injury and distortion of the anatomic landmarks or an obese patient with nonappreciable landmarks.^{14,29} The longitudinal incision in these cases allows for better identification of landmarks followed by continuation of a traditional cricothyroidotomy.

A rush of air will be heard and bubbling seen from the incision once the cricothyroid membrane has been incised and the airway entered with the scalpel. This is true if the patient is ventilating spontaneously or with the assistance of a bag-valve-mask device. **Do not remove the scalpel.** Insert the tracheal hook along the scalpel until it contacts the posterior tracheal wall (**Figure 32-7B**). Rotate the hook superiorly 90° and grasp the inferior border of the thyroid cartilage. Elevate the tracheal hook to retract the thyroid cartilage anteriorly and superiorly (**Figure 32-7B**).^{7,8} The scalpel may now be removed.

The incision site must be expanded to accommodate the passage of an endotracheal tube or a tracheostomy tube. Insert the jaws of a Trousseau dilator or 6 inch hemostat through the cricothyroid membrane in the midsagittal plane while controlling the airway with the tracheal hook (**Figures 32-7C**). Open the jaws of the instrument to dilate the opening in the sagittal plane or vertically.^{7,8,10,11} Close the jaws of the dilator. Rotate the dilator 90° within the incision. Open the jaws of the dilator to dilate the incision in the transverse plane or horizontally. Remove the dilator while continuing to maintain control of the airway with the tracheal hook.

Select a tracheostomy tube that is of an appropriate size for the patient, typically a size 6. An endotracheal tube can be used as an alternative to the tracheostomy tube. Instruct an assistant to lubricate the obturator and outer cannula. Have the assistant insert the obturator into the outer cannula. Insert the tracheostomy tube perpendicularly or 90° to the skin while controlling the airway with the tracheal hook (**Figure 32-7D**). Continue to advance the tracheostomy tube with a semicircular motion and inferiorly until the flange is against the skin. The tracheostomy tube should pass with minimal difficulty. Remove the tracheal hook. Securely hold the outer cannula.

FIGURE 32-7. A surgical cricothyroidotomy. **A.** The nondominant hand stabilizes the cricothyroid membrane. A transverse incision is made through the skin, subcutaneous tissue, and cricothyroid membrane. **B.** A tracheal hook has been inserted over the scalpel blade to grasp the inferior border of the thyroid cartilage. The hook is lifted anteriorly and superiorly to control the airway (arrow). **C.** A Trousseau dilator is inserted into the incision and opened to dilate the incision site. **D.** A tracheostomy tube is inserted through the cricothyroid membrane.

Remove the obturator, insert the inner cannula, inflate the cuff of the tracheostomy tube, connect the bag-valve device, and ventilate the patient.⁷ Confirm the intratracheal position of the tube by auscultating bilateral breath sounds, noting the absence of breath sounds over the stomach, and performing a colorimetric or quantitative end-tidal CO₂ assessment. Secure the tube.

ALTERNATIVE SURGICAL TECHNIQUE

An alternative surgical approach to a cricothyroidotomy was first developed by Oppenheimer.³⁰ It is simpler, more rapid, and easier to perform than the traditional technique described above (Figures 32-8 and 32-9). The technique has been modified from the original description.³¹

Clean, prepare, and drape the neck. Position the nondominant hand with the thumb on one side of the thyroid cartilage and the middle finger on the other side (Figures 32-8A and 32-9A). Identify the anatomic landmarks. Leave the nondominant index finger over the cricothyroid membrane. Infiltrate local anesthetic solution subcutaneously over the cricothyroid membrane if the patient is awake.

Guide a #11 blade along the nondominant index finger and into the cricothyroid membrane making a stab incision (Figures 32-8A, 32-8B, and 32-9B). **Do not insert the scalpel blade more than 1.5 to 2.0 cm to prevent it from injuring the posterior tracheal wall and esophagus.** It is recommended to hold the scalpel just above the blade with the thumb and index finger like a pencil while stabilizing

your hand with the fifth digit against the patient's skin to prevent it from incising too deep.³¹ Air or bubbles from the incision signify entrance into the trachea. **Do not remove the scalpel blade.** Extend the incision laterally 0.5 to 0.75 cm to extend the incision (Figures 32-8C and 32-9C). Rotate the scalpel blade 180° and extend the incision 0.5 to 0.75 cm in the opposite direction (Figures 32-8D and 32-9D). **Do not remove the scalpel blade. Removing the scalpel from the incision will result in losing the landmarks and the location of the incision through the cricothyroid membrane.**

With the scalpel blade in place, guide the tracheal hook down the blade and into the trachea until the posterior wall of the larynx is encountered. The blunt end of the hook will not cause damage to the tracheal mucosa. This will help confirm proper placement inside the trachea and avoid creation of a false passage. Rotate the hook superiorly 90° until the thyroid cartilage is grasped and secured (Figures 32-8E and 32-9E). Lift the tracheal hook superiorly and then anteriorly to elevate and expose tracheal lumen (Figures 32-8F and 32-9F). **Remove the scalpel from the incision only after the airway is controlled with the tracheal hook.**

The incision site must be expanded to accommodate the passage of an endotracheal or tracheostomy tube. Insert the jaws of a Trousseau dilator or a 6 inch hemostat through the cricothyroid membrane in the midsagittal plane while controlling the airway with the tracheal hook (Figures 32-8G and 32-9G). Open the jaws of the instrument to dilate the opening in the sagittal plane or vertically (Figure 32-9H). Close the jaws of the dilator. Rotate the dilator 90°

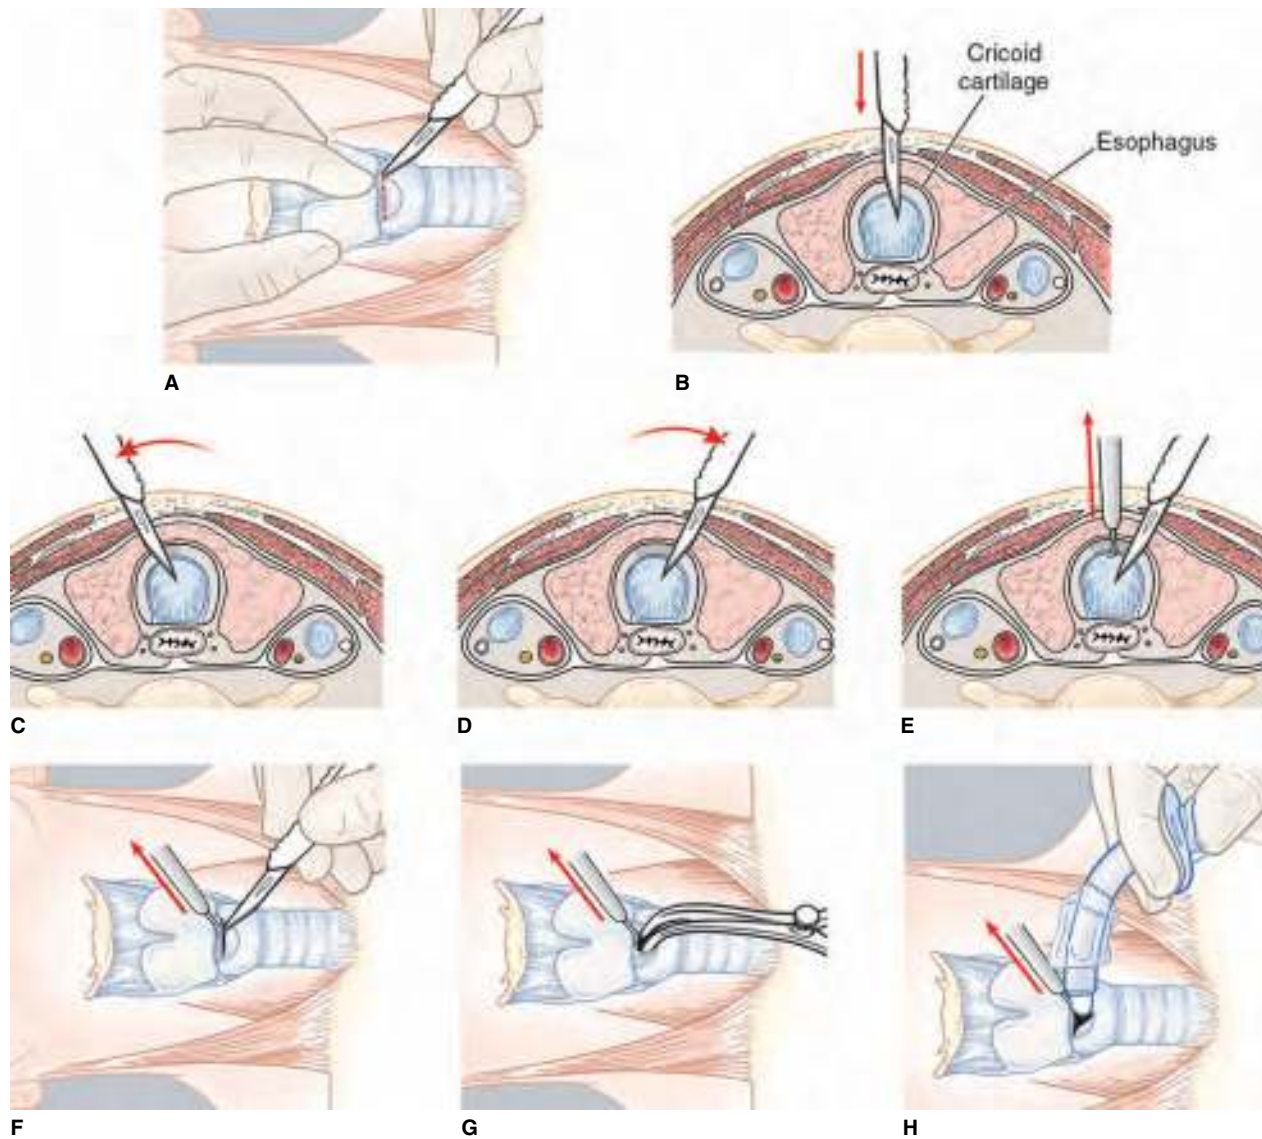

FIGURE 32-8. An alternative method to perform a surgical cricothyroidotomy. **A.** The thyroid cartilage is secured while a stab incision is made in the cricothyroid membrane. **B.** The scalpel blade penetrates the midline and enters the airway. **C.** The incision is extended laterally from the midline. **D.** The scalpel is rotated 180° and extends the incision to the other side. **E.** A tracheal hook is inserted in the midline and grasps the inferior border of the thyroid cartilage. **F.** The thyroid cartilage is lifted anteriorly and superiorly to control the airway (arrow). After the airway is controlled, the scalpel is removed. **G.** A Trousseau dilator is inserted into the incision and the jaws are opened to dilate the incision. **H.** A tracheostomy tube is inserted into the trachea using a semicircular motion before the tracheal hook is removed.

within the incision (**Figure 32-9I**). Open the jaws of the dilator to dilate the incision in the transverse plane or horizontally (**Figure 32-9J**). Insert an endotracheal or tracheostomy tube through the incision and caudally into the trachea (**Figures 32-8H and 32-9K**). If using an endotracheal tube, be sure not to insert it entirely as bronchial intubation and trauma can occur.

Hold the tube securely at the skin and remove the tracheal hook. Inflate the cuff of the endotracheal tube, connect the bag-valve device, and ventilate the patient.⁷ Confirm the intratracheal position of the tube by auscultating bilateral breath sounds, noting the absence of breath sounds over the stomach, and performing a colorimetric or quantitative end-tidal CO₂ assessment. Secure the tube.

PATIENTS WITH MASSIVE NECKS DUE TO SWELLING OR OBESITY

Patients may present with massive neck swelling secondary to edema, hemorrhage, hematomas, obesity, or subcutaneous emphysema after trauma.³² These patients often have no palpable anatomic

landmarks in the neck, making it difficult to create a surgical airway.³³ The traditional surgical methods used to perform a cricothyroidotomy are not practical due to difficulty in identifying the anatomic landmarks and hemorrhage. A technique has been developed to perform a cricothyroidotomy in these patients.³⁴⁻³⁶

The location of the hyoid bone must be determined to use this technique (**Figure 32-10A**). A piece of suture, string, or tracheal tie is required. Place one end of the suture at the angle of the patient's mandible. Run the suture along the mandible and note where it contacts the tip of the chin (**Figure 32-10A**, line 1). Cut the suture at the point where it contacts the tip of the chin. Fold the suture in half. Place one end of the folded suture on the tip of the chin. Pull the other end of the folded suture tight to make a 90° angle to line 1 (**Figure 32-10A**, line 2). Draw an imaginary line from the free end of the folded suture to the angle of the patient's mandible (**Figure 32-10A**, line 3). This third line is the line used to identify the hyoid bone.

Insert a #11 scalpel blade through the midline of the neck in an upward and posterior direction along line 3 (**Figure 32-10B**).

Advance the scalpel blade until it meets resistance when it contacts the hyoid bone. Alternatively, a spinal needle can be inserted along line 3 until it contacts the hyoid bone (**Figure 32-10C**). Insert the #11 scalpel along the track of the spinal needle until the hyoid bone

is contacted. **Do not remove the scalpel.** Insert a tracheal hook along the scalpel blade until the hyoid bone is contacted. Move the tip of the tracheal hook under the hyoid bone (**Figure 32-10D**). Lift the tracheal hook anteriorly and superiorly to elevate and control

the airway (Figure 32-10D). **Do not release the hold of the tracheal hook on the hyoid bone.** Remove the scalpel from the incision.

Make an incision inferiorly and in the midline starting at the site where the tracheal hook exits the skin. **Extend the incision directly inferiorly without regard to the anatomy of the neck. Do not release the tension on the tracheal hook.** Identify the cricothyroid membrane. Make a transverse incision through the cricothyroid membrane. Dilate the opening and insert a tracheostomy tube or endotracheal tube into the trachea as described previously.

SELDINGER TECHNIQUE

A percutaneous cricothyroidotomy kit is available from several manufacturers. One of the more commonly used kits is the Melker Percutaneous Cricothyrotomy Set (Cook Inc., Bloomington, IN). It is a self-contained kit that may be used in the prehospital setting, Emergency Department, or Operating Room. It contains percutaneous needles, a catheter-over-the-needle, a syringe, a #15 scalpel blade, percutaneous airway catheters, dilators that fit inside the

FIGURE 32-10. Cricothyroidotomy in a patient with neck swelling. **A.** Locate the hyoid bone. Line 1 is from the angle of the mandible to the tip of the chin. Line 2 is half the length of line 1 and perpendicular to it. Line 3 is from the end of line 2 to the angle of the patient's mandible. **B.** A #11 scalpel blade is inserted in the midline and aimed along line 3 until it contacts the hyoid bone. **C.** An alternative method. A spinal needle is used to locate the hyoid bone. A #11 scalpel blade is inserted along the tract of the spinal needle until the hyoid bone is contacted. **D.** A tracheal hook is inserted along the scalpel blade and used to grasp the hyoid bone. The tracheal hook is lifted (arrow) anteriorly and superiorly to elevate and control the airway.

airway catheters, a 30 cm flexible guidewire, and a tracheal tie (**Figure 32-11**). The dilator was developed to fit inside the airway catheter (**Figure 32-12**). The dilator and airway catheter are inserted as a unit during the procedure.

The percutaneous cricothyroidotomy kit can be used to establish an airway using a modification of the Seldinger technique.^{14,37,38} This technique can be used to establish an airway in approximately the time it takes to create a surgical cricothyroidotomy.^{37,38} A percutaneous cricothyroidotomy is a simpler and quicker technique for those with little surgical experience with which to establish an airway other than traditional surgical methods. The technique is similar to inserting a central venous line (Chapter 63).³⁹ This technique is familiar and preferred by Emergency Physicians over a surgical cricothyroidotomy.⁴⁰

Clean, prep, drape, and anesthetize the patient's neck. Lubricate the dilator liberally and insert it through the airway catheter (**Figure 32-12**). Lubricate the airway catheter and dilator after it has been assembled into a unit. Stabilize the trachea with

the nondominant hand and identify the landmarks as previously described. Leave the nondominant index finger over the center of the cricothyroid membrane.

Make a stab incision just through the skin over the center of the cricothyroid membrane with the #11 scalpel blade (**Figure 32-13A**). Insert the catheter-over-the-needle attached to a 5 mL syringe containing saline through the skin incision aiming inferiorly (**Figure 32-13B**). Insert and advance the catheter-over-the-needle at a 30° to 45° angle to the skin (**Figure 32-13B**). Advance the catheter-over-the-needle while simultaneously aspirating with the syringe. Stop advancing the catheter-over-the-needle when the airway has been entered. This will be signified by a loss of resistance and air bubbles in the syringe (**Figure 32-13B**).

Hold the syringe securely and advance the catheter over the needle until the hub is at the skin of the neck. Hold the catheter hub securely against the skin of the neck and remove the needle and syringe. Insert and advance the guidewire through the catheter and into the trachea (**Figure 32-13C**). Grasp the guidewire securely

FIGURE 32-11. The contents of a percutaneous cricothyroidotomy kit. (Photo courtesy of Cook Medical, Bloomington, IN.)

FIGURE 32-12. The dilator is placed inside the airway catheter to form a unit.

and remove the catheter over the guidewire (**Figure 32-13D**). **Do not release the hold on the guidewire to prevent it from completely entering the patient's airway.**

Insert the dilator/airway catheter unit over the guidewire and into the trachea in a semicircular motion (**Figure 32-13E**). The tip of the dilator is rigid. **Insert it gently to prevent injury to or perforation of the posterior tracheal wall by holding it 1 to 2 cm from the skin.** Continue to advance the unit until the flange is against the skin of the neck. Hold the airway catheter securely. Remove the guidewire and dilator as a unit, leaving the airway catheter in place (**Figure 32-13F**). Begin ventilation of the patient and secure the airway catheter.

NEEDLE CRICOTHYROIDOTOMY

Perform a needle cricothyroidotomy instead of a surgical cricothyroidotomy in children less than 8 to 10 years of age. A surgical cricothyroidotomy is technically more difficult. The child has a laryngeal prominence that is difficult to palpate as it is not well developed. The cricothyroid membrane is small and often will not allow the passage of an airway tube. The larynx is anatomically positioned relatively higher than in an adult and is more difficult to access. A commercially available kit (ENK Oxygen Flow Modulator Set, Cook Medical, Bloomington, IN) (**Figure 32-14**), a reinforced large-bore catheter (Emergency Transtracheal Airway Catheter, Cook Medical, Bloomington, IN) (**Figure 32-15**), or commonly available equipment in the Emergency Department may be used to perform this procedure.

Stand at the side of the bed and adjacent to the patient's head and neck.¹⁴ **Reidentify the anatomic landmarks. This is crucial to performing this procedure.** Use the nondominant hand and place the

FIGURE 32-13. The percutaneous cricothyroidotomy. **A.** A stab incision is made in the midline over the cricothyroid membrane. **B.** A catheter-over-the-needle is inserted at a 30° to 45° angle to the skin and advanced inferiorly. Negative pressure is applied to a saline-containing syringe during catheter insertion. Air bubbles in the saline confirm intratracheal placement of the catheter. **C.** The catheter has been advanced until the hub is against the skin. The needle and syringe have been removed. A guidewire is inserted through the catheter. **D.** The catheter has been removed, leaving the guidewire in place. **E.** The dilator/airway catheter unit is advanced over the guidewire and into the trachea. **F.** The guidewire and dilator have been removed, leaving the airway catheter in place.

FIGURE 32-14. The ENK Oxygen Flow Modulator. (Photo courtesy of Cook Medical, Bloomington, IN.)

thumb on one side of the thyroid cartilage and the middle finger on the other side. Use these fingers to stabilize the larynx.^{11,27} Use the index finger to identify the anatomic landmarks.^{7,8,14} Start at the laryngeal prominence (i.e., Adam's apple) and move inferiorly. The soft membranous defect inferior to the laryngeal prominence is the cricothyroid membrane. Below this is the cartilaginous ring of the cricoid cartilage.

Attach a 12 to 16 gauge catheter-over-the-needle (i.e., angiocatheter) onto a 5 or 10 mL syringe containing 5 mL of sterile saline. Insert the catheter-over-the-needle through the skin, subcutaneous tissue, and inferior aspect of the cricothyroid membrane. The lower left quadrant of the cricothyroid membrane is the preferred site, as this region is least likely to contain cricothyroid arteries and veins.⁴¹ Direct the catheter-over-the-needle inferiorly and at a 30° to 45° angle (**Figure 32-16A**). Aspirate with the syringe as it is advanced (**Figure 32-16B**). Continue to advance the catheter-over-the-needle while maintaining negative pressure until air bubbles are visible in the syringe and a loss of resistance is felt. These both signify that the catheter-over-the-needle is within the trachea.

The catheter-over-the-needle is within the trachea. Securely hold the needle and advance the catheter until the hub is against the skin (**Figure 32-16C**). Remove the needle and syringe (**Figure 32-16C**). Reattach the syringe without the needle to the catheter. Aspirate once again to reconfirm placement of the catheter within the trachea. The 2 to 3 cm catheter is long enough to pass into the trachea without sitting against the posterior wall. **There is the risk of forcing air submucosally if the catheter tip directly touches or faces the posterior**

FIGURE 32-15. The Emergency Transtracheal Airway Catheter. (Photo courtesy of Cook Medical, Bloomington, IN.)

tracheal wall. Grasp and hold the catheter hub firmly at the skin of the neck. Remove the syringe. Attach the oxygen tubing to the catheter (**Figure 32-16D**). Begin ventilation and continue until a more permanent and secure airway is established.

The patient may be oxygenated and ventilated by several methods. The first involves inserting the adapter piece from a #3.0 endotracheal tube to the catheter hub and then connecting it directly to the bag-valve device or a ventilator. This method allows for the confirmation of breath sounds and provides better ventilation of the patient. The second method involves direct connection of the high-flow oxygen tubing to the hub of the catheter. This method requires cyclic ventilation for 1 to 2 seconds followed by exhalation for 4 to 5 seconds.²⁵ This method provides adequate oxygenation, less adequate ventilation, and is more labor-intensive.

The Ventrain (Dolphys Medical, Eindhoven, The Netherlands) was developed to attach to the Luer lock of its proprietary catheter or other catheter (**Figure 32-17**). The other end attaches to a high-flow oxygen source. The single-use device provides a form of jet ventilation. The minute ventilation depends on the flow rate of the oxygen, the properties of the lungs, and the airways being ventilated. It was designed for difficult or obstructed airways. The Ventrain reduces the risk of intrapulmonary pressure building up and air trapping using expiratory ventilation assistance (EVA). It uses suction during expiration to actively remove gas from the lungs. The device can also be attached to an airway exchange catheter or a bronchoscope. An additional side connector connects to an end-tidal CO₂ monitor.

Confirm the presence of breath sounds with ventilations. Secure the catheter to the skin. This may be done with nylon sutures or strips of adhesive tape. **The patient should undergo orotracheal intubation or a formal tracheostomy as soon as possible because of the risk of dislodging the catheter and the suboptimal ventilation associated with this technique.**

FOUR-STEP TECHNIQUE

A rapid four-step technique (RFST) is preferred by some Emergency Physicians. The steps include the identification of landmarks, making the horizontal incision, placing the tracheal hook, and inserting the tube.⁴²⁻⁴⁵ There is a theoretical risk of increased complications using this technique.⁴²⁻⁴⁵ This has not been the case in humans.⁴ The advantages are the short time to perform the procedure, the requirement of only one person, the elevation of the cricoid cartilage with an easier route to insert the tube, and the performance from the head of the bed. It does not work well in obese patients and patients with swelling.

ALTERNATIVE TECHNIQUES

An endotracheal tube can be used if a tracheostomy tube is not available. The endotracheal tube is much longer than is needed. Remove the 15 mm connector from the proximal end of the endotracheal tube. Cut the endotracheal tube with scissors just above where the cuff port tubing enters the endotracheal tube. Place the 15 mm connector on the shortened endotracheal tube. This eliminates some dead space and makes the endotracheal tube easier to manage. The procedure to insert an endotracheal tube is the same as that for a tracheostomy tube.

A cricothyroidotomy is a seldom performed procedure. A tracheal hook may not be immediately available or found when one is required (**Figure 32-18A**). A simple alternative is to make one using a 16 or 18 gauge needle, a 10 mL syringe, and a hemostat or needle driver (**Figure 32-18B**). Securely apply the needle onto the syringe. Use the hemostat or needle driver to place two 90° bends in the distal needle (**Figure 32-18B**). The syringe acts as a handle and the bent needle as a tracheal hook.

FIGURE 32-16. Insertion of the transtracheal catheter. **A.** The catheter-over-the-needle is inserted 30° to 45° to the perpendicular (*dotted line*) and aimed inferiorly. **B.** Application of negative pressure (*arrow*) to a saline-containing syringe during catheter-over-the-needle insertion. Air bubbles in the saline confirm intratracheal placement of the catheter. **C.** The catheter is advanced until the hub is against the skin. The needle and syringe are then removed. **D.** High-pressure oxygen tubing is attached to the catheter, and ventilation is begun.

Numerous other cricothyroidotomy kits are available (**Table 32-1**). The QuickTrach (Rusch Inc. of Teleflex Medical, Research Triangle Park, NC) is a preassembled, one-piece device (**Figure 32-19**). The SurgiCric Set (VBM Medizintechnik GmbH, Germany) is preassembled but requires the use of an obturator (**Figure 32-20**). The Control-Cric (Pulmodyne, Indianapolis, IN) is a surgical device (**Figure 32-21**).⁴⁶ It consists of the dual-sided Cric-Knife and the Cric-Key with a stylet and cuffed airway. These devices are quick

and simple to use and do not require the use of a guidewire or the Seldinger technique. These are more likely to be used in the prehospital setting than in the Emergency Department.

The use of a bougie or endotracheal tube introducer may aid the performance of a surgical cricothyroidotomy (**Figure 32-22**).⁴⁷ Begin the procedure as described previously. Once the airway is controlled with the tracheal hook, insert a bougie or endotracheal tube introducer inferiorly with its beveled end through the incision

FIGURE 32-17. The Ventrain. (Photo courtesy of Dolphys Medical, Eindhoven, The Netherlands.)

and into the trachea (**Figure 32-22A**). The bougie or endotracheal tube introducer will provide tactile feedback as it crosses the tracheal rings. **It is very important to confirm placement into the tracheal lumen as creating a false lumen or passage into subcutaneous tissue can be devastating.** Advance the tracheostomy or endotracheal tube over the bougie or endotracheal tube introducer and into the trachea (**Figure 32-22B**).

A major advantage of bougies and endotracheal tube introducers is their length. They will not pull out and will ensure that the tract is not lost. It may be more difficult to “railroad” a tracheostomy tube over a bougie because of the tracheostomy tube’s fixed 90° angle. This method will most likely be easier with an endotracheal tube.²⁹

Several quick assembly and low-cost needle cricothyroidotomy setups can be put together quickly with commonly available equipment in the Emergency Department.⁴⁸ Insert a catheter-over-the-needle into the patient’s neck as previously described. Securely hold the hub of the catheter against the skin. Remove the needle and leave the angiocatheter through the skin and into the airway. Attach and connect one of the following to the hub of the catheter. The first consists of a 3.5 mm endotracheal tube respiratory adapter and a bag-valve device. The second consists of a 10 mL syringe without

FIGURE 32-18. The tracheal hook. **A.** Commercial unit. **B.** “Homemade” tracheal hook.

FIGURE 32-19. The Rusch QuickTrach. (Photo courtesy of Teleflex Medical, Research Triangle Park, NC.)

the plunger, a 7.0 mm endotracheal tube inserted into the syringe, and a bag-valve device. The third consists of a 3 mL syringe without the plunger, a 7.0 mm endotracheal tube respiratory adapter, and a bag-valve device. The fourth consists of the cut distal 10 cm of intravenous infusion tubing, a 2.5 mm endotracheal tube respiratory adapter, and a bag-valve device.

ASSESSMENT

Confirm the proper positioning of the tube (Chapter 19). Use auscultation of bilateral breath sounds, chest rise, and end-tidal CO₂ monitoring. Obtain a chest radiograph to confirm the position of the tube and rule out the presence of a pneumothorax.²⁵

AFTERCARE

Hold the tracheostomy in place firmly while the patient is ventilated with a bag-valve device or a ventilator.¹⁴ **Do not release the hold on the tracheostomy tube until it is secured.** Obtain hemostasis of the wound edges by grasping any bleeding vessels with a hemostat and placing an absorbable 3–0 suture over the vessel. Pack the wound with iodoform gauze if the skin incision is significantly larger than the tracheostomy tube. Secure the tracheostomy tube by placing

FIGURE 32-20. The SurgiCric. (Photo courtesy of VBM Medizintechnik GmbH, Germany.)

FIGURE 32-21. The Cric-Knife (*left*) and the Cric-Key (*right*). (Photo courtesy of Pulmonary, Indianapolis, IN.)

twill tape (i.e., tracheostomy tape) through one flange, around the patient's neck, and through the other flange.^{14,25} An alternative is to suture the four corners of the tracheostomy flanges to the patient's skin using a 3-0 nylon suture.

Secure an endotracheal tube if it was inserted instead of a tracheostomy tube. Wrap tape around the endotracheal tube as it exits the incision site. Wrap the tape around the patient's neck and back onto the endotracheal tube. Alternatively, a commercially available endotracheal tube holder can be used to secure the tube.

The tracheostomy or endotracheal tube can be removed easily when the indication for airway control no longer exists. This usually occurs after the patient is orotracheally intubated or nasotracheally intubated or has a formal tracheostomy performed. Place an occlusive dressing (e.g., petroleum gauze) over the incision after removal of the tube and until it heals. It is advised that the cricothyroidotomy be converted to a formal tracheostomy to minimize the risk of long-term complications if the patient is predicted to require ventilatory management for more than 7 days.

COMPLICATIONS

Complications following a cricothyroidotomy can be classified as early or late based on when they occur. Early complications will be recognized either immediately after the performance or within a few hours. Late complications may not be apparent for weeks to months following the procedure. There are numerous complications associated with performing a cricothyroidotomy (Table 32-2).^{5,7,9,11,12,14,26,27,49,50} These are often due to performing a cricothyroidotomy under stressful conditions.

The most serious early complication is malposition of the tracheostomy tube within the soft tissues of the neck. The patient cannot be ventilated or oxygenated if the tube is not within the trachea. This is easily recognized by auscultating the chest. It should

A

B

FIGURE 32-22. Using a bougie for a cricothyroidotomy. **A.** The bougie is inserted into the trachea. **B.** An endotracheal tube has been placed over the bougie and advanced into the trachea. (Photo used with permission from reference 47.)

be noticed immediately by resistance on manual ventilation with a bag-valve-mask device. It can be remedied by removing the tracheostomy tube and replacing it in its proper location. The tube may be misplaced above or below the cricothyroid membrane. Placement above the cricothyroid membrane often results from inadequate palpation of landmarks and is associated with an incision into the larynx. Convert the airway as soon as possible to a tracheostomy once this malposition is recognized.⁹ Placement below the cricoid cartilage has been estimated to occur in 10% of cricothyroidotomies.⁵ There is no specific treatment required for this other than the recognition that the patient has a high tracheostomy.

TABLE 32-2 Complications Associated with Cricothyroidotomy and Preventive Measures

Complication	Preventive measures
Aspiration	Appropriate patient positioning Insert nasogastric tube to decompress stomach Suctioning
Bleeding	Avoid thyroid isthmus Make incision in midline Make incision over cricothyroid membrane
Cartilage (cricoid or thyroid) fracture or laceration	Confirm landmarks and positioning before making incision Know neck anatomy Use small tubes
Creation of a false passage	Assess airflow through tube Confirm landmarks and positioning before making incision Know neck anatomy Monitor oxygenation and ventilation
Dysphonia or hoarseness	Avoid vocal cords Do not force tube inside airway Use small tubes Use tracheal hook
Endotracheal tube in bronchus	Avoid insertion of endotracheal tube too far Use cut endotracheal tube
Esophageal perforation	Do not insert scalpel too deeply
Laryngeal injury	Avoid excessive traction with the tracheal hook Use small tube
Recurrent laryngeal nerve injury	Avoid posterior tracheal wall Make incision in midline
Subglottic stenosis	Avoid long-term use Use small tube
Thyroid membrane incision	Confirm landmarks and positioning before making incision Know neck anatomy
Tracheal stenosis	Remove as soon as possible Use low-pressure cuff
Tube dislodgement	Cut endotracheal tube Maintain control of tube until secured Monitor insertion depth
Tube occlusion	Monitor ease of ventilation Monitor pulse oxygenation

Laryngeal injury may occur if the tracheostomy tube that is inserted is larger than the cricothyroid membrane. The cricothyroid membrane is only 9 to 10 mm in height in the average adult.^{11,14} Placement of a tracheostomy tube with a larger outer diameter may cause a fracture of the thyroid cartilage. It is important that the tracheostomy tube placed is no larger than a #6.0 or a #7.0.^{11,14} Placement of a larger tube is associated with an increased incidence of subglottic granulation and stenosis.^{5,7}

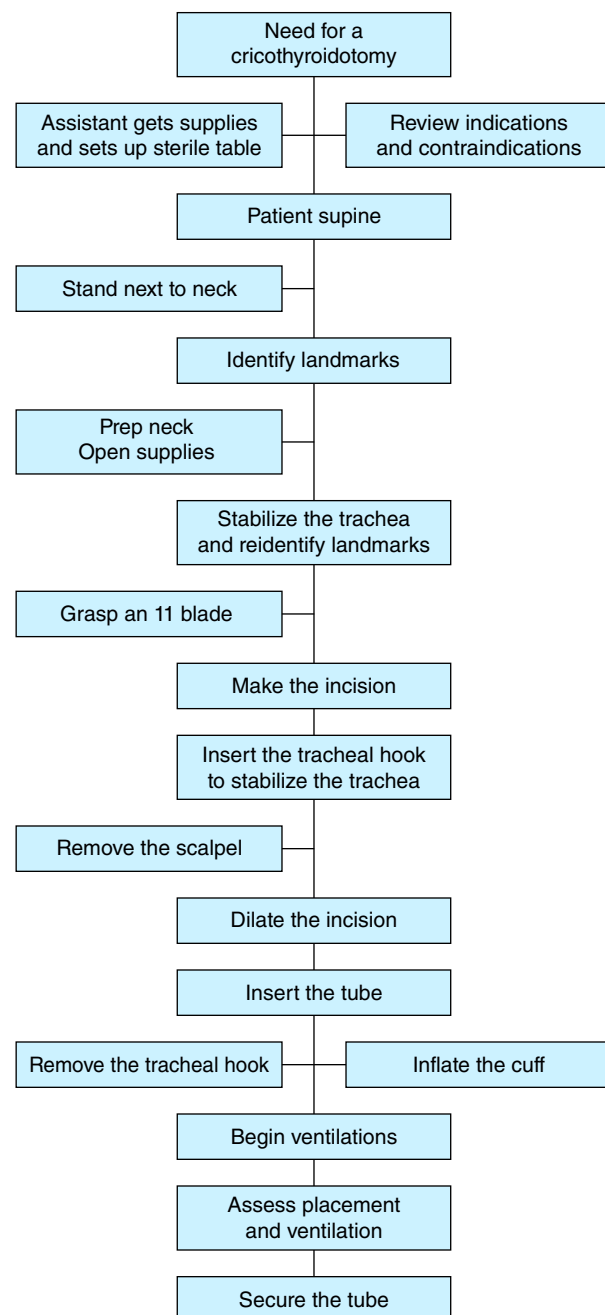

Incisional bleeding occurs in 4% to 8% of patients following a cricothyroidotomy.^{5,7,9,11,49} This may result from transection of the anterior jugular veins if the incision extends too far laterally. Bleeding is usually easily treated by suture ligation of the bleeding vessels and packing around the tracheostomy tube with iodoform gauze. A small amount of bleeding or oozing from the cricothyroid arteries can be tamponaded by packing iodoform gauze around the tracheostomy tube. Blood can occlude the tube.⁵¹

An emergent cricothyroidotomy is usually performed in less than sterile circumstances. There is a risk of developing a wound infection.⁴⁹ This is usually the result of skin flora. It can often be treated with wet-to-dry saline dressing changes. In some cases, the infection will not resolve until the cricothyroidotomy tube has been removed. This is done by decannulation or conversion to a formal tracheostomy. Antibiotics are usually not required.

Late complications take two general forms: progressive airway obstruction and chronic voice changes. Patients with progressive

airway obstruction present with slowly increasing stridor and dyspnea weeks to months after the procedure. This usually results from subglottic stenosis and granulation tissue formation at the site of the stoma.^{5,9,26} It is unclear whether this complication results from the cricothyroidotomy or the tracheostomy tube. The majority of these patients have had prolonged endotracheal intubations before the cricothyroidotomy or prolonged tracheostomy placement after the cricothyroidotomy.^{5,26,27,50} In one series, patients with a cricothyroidotomy for a prolonged period (average 72 days) had a 52% incidence of chronic obstruction compared to no obstruction in patients with cricothyroidotomy for a shorter period (average 27 days).⁵⁰ Another study recommended that the tracheostomy tube be removed by the fourth day to minimize these long-term complications.¹²

A final late complication is that of voice changes. This has been described in up to 25% of patients who received a cricothyroidotomy.^{9,26,27,49} Many of these patients had other methods of airway management either before or after the cricothyroidotomy.

**FIGURE 32-23.** An algorithm for performing a cricothyroidotomy.

Voice changes tend to be somewhat nonspecific. Patients will complain of decreased volume, fatigue, and hoarseness. These changes may be due to small amounts of granulation tissue at the stoma site and generally resolve over time.⁷

SUMMARY

A cricothyroidotomy is a potentially lifesaving airway management technique. It is an important procedure for the Emergency Physician to be skilled in, as it may represent the only access to the patient's airway. It can be used to provide oxygenation and ventilation to a patient when other less invasive airway control methods have failed or are contraindicated. It is a reliable, relatively safe, and a simple procedure that can be performed within a few minutes (**Figure 32-23**). Self-contained percutaneous and surgical cricothyroidotomy kits are commercially available and simple to use. Knowledge of the anatomy of the anterior neck is essential in order to minimize complications.

Tracheostomy

Eric S. Levy and Christopher J. Haines

INTRODUCTION

Control of the airway is the first priority in the resuscitation of a critically ill patient and must be accomplished before any other intervention can proceed. Emergency Physicians are equipped with multiple nonsurgical techniques and devices to secure an airway including orotracheal intubation, nasotracheal intubation, and laryngeal mask airways. Unfortunately, there are cases in which these methods become impossible or are contraindicated. In these instances, a surgical airway must be obtained and can be accomplished by performing a cricothyroidotomy or tracheostomy. Cricothyroidotomy is described in Chapter 32. This chapter will focus on the indications, technique, and complications for a tracheostomy.

A tracheostomy is the surgical creation of an opening into the trachea, while a cricothyroidotomy refers to the more permanent procedure of bringing the tracheal mucosa into contact with the skin of the neck.¹⁻³ The most traditional role for a tracheostomy is as an elective procedure done in patients with the need for a prolonged artificial airway. The role of a tracheostomy for emergent airway access has diminished as newer, safer, and equally effective techniques have evolved.

Familiarity with the methods to perform a tracheostomy is still valuable. Knowledge of proper techniques, possible indications, limitations, and likely complications will guide one's judgment in critical moments when it most counts. Understanding the procedure for a tracheostomy will allow Emergency Physicians to properly care for a problem or complication when a patient with a tracheostomy tube presents to the Emergency Department.

ANATOMY AND PATHOPHYSIOLOGY

A surgical approach to the airway relies upon a sound knowledge of the anatomy of the neck and a safe approach to the trachea. **A careful review of this anatomy illustrates how critical it is to remain in the midline in order to avoid morbidity and mortality.** External landmarks are useful in identifying the significant structures of the airway (Figure 33-1).^{4,5} The laryngeal prominence is a useful guide to the thyroid cartilage. The cricoid cartilage can be identified as a ring just inferior to the thyroid cartilage. In the absence of

FIGURE 33-1. Lateral view of the topographic anatomy of the neck.

edema or a hematoma, a finger marched down the midline from the cricoid cartilage can palpate and identify the cartilaginous rings of the trachea. In an emergent situation, these external landmarks may be all a physician has to guide the establishment of a surgical airway.

The neck is a complex three-dimensional structure with numerous vital structures coursing through a small space (Figures 33-2 through 33-6). The cervical portion of the airway is anterior, superficial, and midline. It is covered by skin, subcutaneous tissue, and numerous muscles (Figure 33-2). The basic cartilaginous framework of the airway begins superiorly at the hyoid bone and continues inferiorly with the larynx and trachea (Figure 33-3). The external skeleton of the larynx comprises the hyoid bone, thyroid cartilage, and cricoid cartilage.⁶ The hyoid bone is a U-shaped structure attached to the mandible, tongue, and base of the skull by muscles. It is the most stable portion of the airway. Even in the presence of pathology, the hyoid bone is remarkably constant in position and can be considered a stable landmark.⁷⁻⁹

The larynx is easy to identify externally. The prominent thyroid cartilage forms the laryngeal prominence (i.e., the Adam's apple) at its inferior pole (Figure 33-3). It is a freely mobile structure that is anchored by muscles and moves with deglutition. Airway manipulation done on an awake patient will need to fix the larynx to avoid involuntary movement of the larynx from reflex swallowing. The thyroid cartilage is attached to the cricoid cartilage via the cricothyroid membrane (Figure 33-3). This is the site for a cricothyroidotomy and can be identified by palpating a slight indentation inferior to the laryngeal prominence. The cricoid is signet ring-shaped and is the only complete cartilaginous ring in the airway. **Procedures should avoid damage to the cricoid cartilage, fearing a loss of stability in the airway.** The cricotracheal ligament attaches the cricoid cartilage to the trachea.

The trachea is a cartilaginous and membranous tube that is approximately 10 to 11 cm long and 2 to 2.5 cm wide in the average adult. In the pediatric patient, the length and width of the trachea will vary depending on the size and age of the child.¹⁰ It extends from the neck into the thorax, where it ends at the carina by dividing into the right and left mainstem bronchi (Figure 33-4). It is made up of 16 to 20 incomplete U-shaped cartilaginous rings anteriorly and laterally. The posterior portion is comprised of a fibromuscular membrane. This membrane attaches the cartilaginous rings to one another and imparts great elasticity in the trachea.² Full extension of the neck adds significant length to the supraclavicular trachea. This feature should be taken advantage of when performing a tracheostomy.¹¹

The trachea is bordered anteriorly by skin, subcutaneous tissue, platysma muscle, pretracheal fascia, and the thyroid gland (Figure 33-5). The pretracheal fascia is the anterior portion of the deep cervical fascia. It descends from the thyroid and cricoid cartilages and splits to enclose the thyroid gland, trachea, and esophagus. The pretracheal fascia continues downward into the thorax and mediastinum. Anterior to the trachea, it is very thin and inconsequential. Laterally, it is extremely thick and blends with the carotid sheath.

The thyroid gland lies anterior to the second through fourth tracheal rings and is inevitably encountered during a tracheostomy. It is a richly vascular structure (Figure 33-6) that receives its blood supply from the superior thyroid artery (a branch of the external carotid artery) and the inferior thyroid artery (a branch of the thyrocervical trunk). These vessels anastomose into a rich plexus on the anterior surface of the thyroid gland. These major arteries do not usually cross the midline.

Unfortunately, the midline is not always free of blood vessels. An unpaired thyroid ima artery will occasionally be found in the

FIGURE 33-2. The superficial muscles and airway structures in the neck.

midline to supply the isthmus of the thyroid gland. The anterior thyroid veins often form a vascular arch across the midline and just inferior to the thyroid gland. A hastily performed tracheostomy or one carried out under difficult conditions may encounter significant hemorrhage from transected vessels.

A number of vital structures surround the trachea and are at risk for injury during a tracheostomy. Their positions relative to one another are best appreciated in a cross-sectional view of the neck (**Figure 33-5**). The deep strap muscles, the sternohyoid and sternothyroid, run adjacent to the trachea and may have to be reflected away for adequate visualization (**Figure 33-2**). The

right and left lobes of the thyroid gland encase the upper trachea (**Figures 33-5 and 33-6**) with the thyroid isthmus crossing anteriorly from the second to the third tracheal rings.² Close to the thyroid lobes, the recurrent laryngeal nerves run vertically on both sides of the trachea. **These nerves are particularly vulnerable when dissection is extended laterally.**¹² The common carotid artery, internal jugular vein, and vagus nerve are contained by the carotid sheath and lie adjacent to the thyroid gland. The carotid sheath lies extremely close to the trachea in infants and has been mistaken for the trachea in emergent situations.¹² The innominate or brachiocephalic artery crosses left to right immediately anterior to the trachea, while the

FIGURE 33-3. The framework of the airway in the neck.

FIGURE 33-4. The cartilaginous framework of the airway.

esophagus lies immediately posterior to the trachea. Erosion of the anterior tracheal wall can occur with prolonged tracheostomy tube placement, leading to a tracheoinnominate artery fistula. The parietal pleura can be found on either side of the trachea at the sternal notch and is also at risk of injury during a tracheostomy.

FIGURE 33-5. Cross-sectional anatomy of the neck at the level of the isthmus of the thyroid gland.

FIGURE 33-6. Vascular structures supplying and surrounding the thyroid gland.

INDICATIONS

The tracheostomy is an ancient and time-honored technique for securing and maintaining an artificial airway. The American Academy of Otolaryngology–Head and Neck Surgery has proposed specific clinical indicators for the use of a tracheostomy (**Table 33-1**).¹³ A number of indications for tracheostomy are widely accepted (**Table 33-2**).^{7,11-20} As mentioned previously, a tracheostomy is generally considered an elective procedure done under nonemergent conditions after the airway has been secured by other techniques.²¹⁻²⁵ Its use as an emergency procedure is controversial. Used by battlefield surgeons during wartime, its reputation as a procedure of last resort is not without reason. **It is fraught with danger when performed under emergency circumstances.**

TABLE 33-1 Clinical Indications for Performing a Tracheostomy, as Proposed by the American Academy of Otolaryngology–Head and Neck Surgery

Adjunct to manage head and neck surgery
Adjunct to manage head and neck trauma
Bilateral vocal cord paralysis
Difficult intubation
Facilitation of ventilation support
Inability of patient to manage secretions
Need for prolonged mechanical ventilation
Obstructive sleep apnea
Upper airway obstruction

Source: Adapted from reference 13.

A tracheostomy is frequently considered in the treatment of upper airway obstructions including angioedema, airway foreign bodies, complex facial fractures, deep space neck infections, epiglottitis, and multiple lacerations to the floor of the mouth. Although these conditions can create serious and immediate airway compromise, the airway can be managed in most cases with orotracheal intubation. **An emergency tracheostomy is not the treatment of choice but rather the choice of last resort.**

There are a few clinical settings in which an emergency tracheostomy should be considered. These include laryngotracheal injury with airway disruption, severe maxillofacial trauma, complete subglottic obstruction, and the need for an airway when all other methods have failed.^{12,26,27} **With the exception of these limited applications, an emergency tracheostomy is discouraged.**^{12,15,28,29}

LARYNGOTRACHEAL TRAUMA

Most head and neck trauma patients can be managed with non-surgical airway techniques. There are a number of options available including orotracheal intubation, nasotracheal intubation, intubation guided by a lighted stylet or “lightwand,” retrograde guidewire intubation, fiberoptic-assisted intubation, and video laryngoscopy. Nasotracheal intubation should be avoided in patients with a

potential head injury. **If a surgical airway is necessary, a cricothyroidotomy is usually the procedure of choice.**

Laryngotracheal injuries are rare but potentially life threatening. When suspected, immediate efforts should focus on getting the patient to the Operating Room. These injuries can result from either blunt or penetrating injury to the neck. They are often accompanied by edema, hemorrhage, subcutaneous emphysema, and fracture of either the thyroid or cricoid cartilages. A tracheostomy should be considered when rapid access to the cricothyroid membrane may be limited, making it difficult to perform a cricothyroidotomy.^{12,30–32} Blunt injury has been described when the anterior neck forcefully strikes a fixed object such as a rope or cable. A classic example of this type of injury is forcefully striking the anterior neck against the steering wheel during high-speed motor vehicle collisions.^{12,31,32} Penetrating injuries to the airway are usually apparent; however, blunt injuries to the trachea require a high index of suspicion.^{32,33} In a review of 51 patients with blunt injury to the trachea, the most common presenting signs and symptoms included dysphonia, hemoptysis, hoarseness, respiratory distress, and subcutaneous emphysema.³² In this same review, a high rate of endotracheal intubation failure was reported with the conclusion that emergent tracheostomy was the best means of airway control.³² In cases of penetrating trauma to the larynx, Emergency Physicians may consider obtaining emergent airway control directly through the wound as a temporary measure prior to operative management.¹⁰

Laryngotracheal disruption, occurring when the larynx and trachea become separated, is an unusual injury. This is the one injury in which a tracheostomy is the undisputed method for establishing and securing the airway. Patients with laryngotracheal disruption may exhibit varying degrees of aphonia, blood-streaked sputum, bruising over the anterior neck, hoarseness, respiratory distress, and subcutaneous emphysema. A defect may be palpable in the patient's neck. Soft tissue radiographs of the neck may reveal an interrupted air column. **If the airway is disrupted, a “low tracheostomy” between the fourth and fifth tracheal rings should be performed.** The severed airway will tend to retract into the thorax, and a low tracheostomy will offer the best chance of securing the dismembered segment. Misguided attempts to visualize the airway, intubate orally, or perform a cricothyroidotomy may further damage the already precarious airway. This is fortunately a rare injury with only a few case reports in the literature.^{26,27} A tracheostomy performed in this setting is more treacherous than usual. **Although a tracheostomy may be the only way to secure the airway, this airway intervention has a better chance of success when performed in the Operating Room.**

SURGICAL AIRWAYS IN THE PEDIATRIC PATIENT

Surgical approaches to the airway are more difficult and complicated in pediatric patients, especially newborns and infants.^{3,34,35} The larynx is positioned more cephalad than in the adult, allowing relative protection by the mandibular arch.¹⁰ It is more anteriorly located and significantly smaller than in adults, as well as more floppy and mobile. The infant's cricothyroid membrane, unlike that of the adult, is extremely narrow and cannot easily be used for access to the airway. For this reason, a surgical cricothyroidotomy should be avoided until a child is older than age 12 years.^{10,12} **Attempts at creating emergency surgical airways in children are typically acts of desperation. A calm and reasoned approach to the pediatric airway and common respiratory problems is essential.** Efforts should first be made to suction the airway clear of secretions followed by ventilation with a bag-valve-mask device. **Direct visualization by laryngoscopy and orotracheal intubation should be attempted before resorting to a surgical airway.** If an unstable patient cannot be ventilated, a needle cricothyroidotomy can serve as a

temporizing measure until a surgical team can be assembled and better control achieved.^{10,12}

In the pediatric population, laryngotracheal injury is rare.¹² Children typically sustain blunt anterior neck injury as the result of high-speed collisions involving bicycles, falls, and motor vehicles. This injury type may be the result of sports-related activity. Clinical signs and symptoms of laryngeal or tracheal trauma mirror that of adults. Airway management in these patients can be achieved with a tracheostomy. However, this may be quite difficult and is only advocated by some authors.¹⁰ **Attempts to obtain surgical assistance should be sought immediately.**

CONTRAINDICATIONS

An emergency tracheostomy is contraindicated when other methods can be used to secure the airway. There are a few instances when an immediate surgical airway is necessary. **Cricothyroidotomy is the procedure of choice when a surgical approach to the airway is required.** A cricothyroidotomy is faster, more direct, relies predominantly on external landmarks, requires only a single operator, can be done with ambient lighting, and requires a limited amount of equipment.^{13,36} **In contrast, a tracheostomy is a procedure requiring multiple steps.** The tracheostomy involves direct visualization to dissect through vascular structures and requires better light than is commonly present at the bedside. A tracheostomy is easier and therefore faster to execute if one has an assistant, proper suctioning equipment, and electrocautery. Without these advantages, the technique is difficult and likely to be complicated. A “timely trach” can be performed within 5 to 10 minutes.¹³ However, reported times to definitive airway during elective open tracheostomies have ranged from 13.5 to 105 minutes.³⁶⁻³⁹ Although this time frame may be adequate for urgent situations, it is too slow for the true emergency in a patient who lacks an airway.

There are numerous relative contraindications and no absolute contraindications.⁴⁰ These are relative as the alternative is death. A known high-riding innominate artery may be injured in the procedure. A coagulopathy or thrombocytopenia can result in uncontrollable bleeding. Fracture of the larynx may result in airway collapse and uncontrolled bleeding. The issue with young children has already been discussed. Infection surrounding the procedure site can compromise the airway or result in spread of the infection. High levels of positive end-expiratory pressure are difficult to maintain. A laryngotracheal disruption may turn into a worse airway nightmare as the distal trachea moves further into the chest. The procedure is more difficult in the morbidly obese patient. Finally, inexperience with the tracheostomy procedure makes it more difficult to perform.

EQUIPMENT

A tracheostomy requires an extensive amount of equipment. Appropriate supplies should be sterilized and assembled in a prepackaged tray. A list of required equipment is given in **Table 33-3**. If such a tray is not available, supplies that are immediately on hand have to suffice. A thoracotomy or major procedure tray will contain most of the required equipment.

PATIENT PREPARATION

Patient preparation will depend largely on the circumstances dictating the procedure. Rapid control will have to be established with a sedative if the patient is uncooperative, hypoxic, or thrashing about. The ideal agent is one that sedates with minimal hemodynamic consequences, preserves spontaneous respirations, and leaves an intact gag reflex (i.e., ketamine). **Procedural sedation and analgesia**

TABLE 33-3 The Supplies Required to Perform a Tracheostomy

Patient preparation	Setup
Cardiac monitor	Povidone iodine or chlorhexidine solution
Pulse oximeter	Surgical drapes to enclose the field
Intravenous line with saline	Sterile gown, gloves, and mask
Oxygen	Hat
Ambu bag for ventilating patient	
Procedure	
Local anesthesia	Two pairs of scissors, one straight and one curved
10 mL syringe	Two tissue forceps without teeth
1% lidocaine	Two Allis forceps, to grasp the trachea
18 gauge needle	Two small rakes, for exposure
25 gauge needle	Mastoid retractor
#10 scalpel blade and handle	Trousseau dilator
#11 scalpel blade and handle	Two tracheal hooks
Two skin forceps	10 mL syringe
Eight small curved hemostats	Umbilical tape
Sterile 4×4 gauze squares, two dozen	Needle holder
Two Kocher forceps (if needed, to clamp the thyroid)	
Frazier suction catheter with suction tubing	
Suture ligatures (3-0 chromic, 3-0 silk, 3-0 nylon)	
Tracheostomy tube, appropriate size for patient	
Water-soluble lubricant or anesthetic jelly	
Suction source and tubing	

(Chapter 159) can cause the patient to stop breathing and worsen the situation. Calm reassurance may allow the procedure to be performed under local anesthesia if the patient is awake and cooperative.⁴¹ A local anesthetic is sufficient if the patient is unconscious.

Place a rolled towel under the patient’s shoulders and neck if no contraindications exist (Figure 33-7). This detail cannot be emphasized enough. Full neck extension brings the airway anterior and increases the length of the supraclavicular trachea by as much as 2.6 cm.^{10,42} It enlarges the surgical field for improved access. Neck extension tends to fix the airway in position and pull it taut. **When the neck is in a neutral or flexed position, the trachea lies more posteriorly and is more “floppy,” it is easier to stray off midline, and the surgical field may be reduced to a dark hole with poor visibility. A certain degree of extension is helpful in the pediatric patient, but full extension may occlude the airway.**

FIGURE 33-7. Optimal patient positioning for a tracheostomy with the neck extended.

FIGURE 33-8. Hand positioning to palpate the anatomic landmarks.

Check the equipment, briefly and quickly, prior to beginning the incision. A tracheostomy tube that is appropriate for the patient's size should be selected. An average male will accommodate a size 7 or 8 Shiley tracheal tube. An average-size female will accommodate a size 6 or 7 Shiley tracheal tube. The cuff of the tracheal tube should be tested prior to use. An endotracheal tube can be used as an alternative to a tracheostomy tube.

Identify the anatomic landmarks required to perform this procedure. Using the nondominant hand, place the thumb on one side and the middle finger on the other side of the patient's trachea (**Figure 33-8**). Identify the laryngeal prominence (i.e., the Adam's apple) with the index finger. Slide the index finger caudally to identify the cricothyroid membrane, the cricoid cartilage, and the tracheal rings.

Clean the neck of any dirt and debris. Even during the resuscitation of an unstable patient, there should be adequate time for the use

of aseptic solution as well as sterile technique. Prepare yourself by applying a hat, mask, eye protection, sterile gown, and sterile gloves. Apply a sterile drape to isolate a surgical field. Infiltrate local anesthetic solution along the planned incision line. It was once thought that injection of local anesthetic into the trachea blunts the cough reflex and provides a sense of depth of the airway. A recent review of 97 patients who underwent an awake tracheostomy noted that this could result in cough, agitation, and less beneficial outcomes.⁴³

Once the patient is positioned, prepped, and anesthetized, establishment of the airway should be just 2 to 3 minutes away. **The last step in preparation should be the mental decision that no other technique will suffice and the commitment to proceed with confidence.**

TECHNIQUE

In the most critical situation, the simplest technique is likely to be the most successful.⁴⁴ The right-handed operator should stand to the patient's right and fix the airway with their nondominant left hand (**Figure 33-8**). Left-handed operators should adjust their technique based on their preference for handedness. Apply the thumb and third digit of the nondominant hand on the thyroid cartilage while the index finger palpates the cricoid and tracheal rings (**Figure 33-8**). An awake or lightly anesthetized patient may swallow or gulp during the procedure, thereby moving the landmarks. Fixing the left hand firmly on the upper airway will minimize this distraction.

A vertical incision is preferred in the emergent setting because it allows greater exposure of the cricothyroid membrane and the trachea and avoids traversing lateral structures.¹² Make a 3 or 4 cm vertical midline incision through the skin and subcutaneous tissues beginning just below the cricoid cartilage and extending inferiorly to the supraclavicular notch (**Figure 33-9**). A larger skin incision causes no harm as long as it remains superficial to avoid damaging the cricoid cartilage. **Extreme care should be taken to ensure that the incision and further dissection remain in the midline.**¹²

Once the skin and subcutaneous tissue have been incised, attention should be directed toward clearing the pretracheal space and defining the tracheal rings. Divide the superficial and deep strap

FIGURE 33-9. The skin incision is made in the midline, beginning below the cricoid cartilage and extending down toward the supraclavicular notch. An incision made with these landmarks will lie over the second through fourth tracheal rings.

FIGURE 33-10. The skin and subcutaneous tissues have been retracted. The strap muscles are divided in the midline to expose the pretracheal space.

muscles in the midline and retract them away from the trachea (**Figure 33-10**). Bluntly dissect free and reflect away any blood vessels in front of the trachea. If they impede progress, they can be clamped with hemostats and divided. The thyroid gland lies above the trachea. Bluntly dissect between it and the trachea with a hemostat to mobilize the thyroid gland (**Figure 33-11**). An alternative option to consider in the emergent setting is to use the nondominant index finger to dissect the pretracheal space bluntly and reflect the thyroid isthmus either superiorly or inferiorly. This minimalist blunt approach lacks finesse but is effective and timely.¹⁵

FIGURE 33-11. The thyroid gland is bluntly dissected from the trachea. Arrows represent movement of the hemostat.

FIGURE 33-12. The thyroid gland is retracted upward and out of the surgical field.

Retract the thyroid gland upward (**Figure 33-12**). If this becomes difficult, it may be faster to divide the isthmus between two hemostats (**Figure 33-13**). The hemostats will limit the bleeding from obstructing the surgical field. The divided edges can be oversewn after the tracheostomy tube is in place. Once the thyroid has been divided, the operating field will be cluttered with hemostats and may be partially obstructed. **Do not apply traction to the instruments as this can avulse tissue and lead to bleeding and further obstruction of the surgical field.**

When ready to make the tracheal incision, it may be helpful to have an assistant place a tracheal hook under the first tracheal ring

FIGURE 33-13. An alternative method of clearing the thyroid gland from the surgical field. The isthmus is clamped and transected.

FIGURE 33-14. A tracheal hook is placed below the first tracheal ring to elevate and immobilize the trachea.

and apply traction superiorly and anteriorly (**Figure 33-14**). Have the assistant hold the tracheal hook in position. This will elevate and immobilize the trachea. The assistant should direct their hands superior to the wound to keep the field unobstructed. If the neck is properly extended, this may be unnecessary. **If at any time identification of the trachea becomes difficult, needle aspiration may be used to confirm the presence of an air-filled tube.**

Make an incision in the trachea. The preferred tracheotomy is a midline vertical incision extending from the second through the fourth tracheal rings (**Figure 33-15A**). There are other options, but they are discouraged in the emergent setting because they stray from the midline (**Figures 33-15B to D**). Insert a Trousseau dilator

FIGURE 33-16. Insertion of the tracheal tube. **A.** The incision is held open with a Trousseau dilator, hemostat, or Allis forceps (shown here) as the tracheostomy tube is inserted. **B.** The tracheostomy tube is advanced and the cuff inflated.

or hemostat into the incision. Use the dilator to open and widen the incision. Alternatively, the sides of the tracheal incision can be grasped and held open with Allis forceps (**Figure 33-16A**).

Liberal lubricate the appropriate-size tracheostomy tube. Insert the tracheostomy tube, with its obturator, through the tracheotomy while the incision is held open (**Figure 33-16A**). Advance the tracheostomy tube and inflate the cuff (**Figure 33-16B**). Hold the tracheostomy tube in place securely. Remove the obturator and insert the inner cannula. Attach a bag-valve device and begin ventilating the patient.

USE OF ULTRASONOGRAPHY

There has been a recent surge of bedside ultrasound in the Emergency Department. A tracheostomy is no exception.⁴⁵⁻⁵⁰ The use of ultrasound improves percutaneous tracheostomy. It allows identification of the landmarks, aids in choosing an appropriate site for the procedure, and is helpful in estimating the distance from the skin to the airway. Ultrasound allows precise localization of the needles and

increases first-pass puncture. It reduces complications and can be used to detect postprocedure complications (e.g., a pneumothorax).

ALTERNATIVE TECHNIQUES

Since 1969, a number of authors have described a third invasive option for airway control, the percutaneous dilatational tracheostomy (**Figure 33-17**).⁵¹⁻⁶⁰ Although techniques vary somewhat, they all rely on an initial puncture of the airway followed by progressive dilatation of a tract. Once a sufficiently large tract is formed, an airway tube is placed. There is now enough evidence to argue that percutaneous tracheostomies are competitive with, and perhaps preferable to, formal open tracheostomies done under elective conditions.^{37,38,61-73} Several large series of percutaneous tracheostomies are now complete, but significant results are available only for elective tracheostomies done in patients who have already been intubated.^{62,64,65,70} There are small case studies that have been published regarding the successful use of percutaneous dilatational tracheostomy in an emergency setting. These authors conclude that percutaneous dilatational tracheostomy is an effective airway, providing an alternative to endotracheal intubation. The resultant airway is stable and does not require conversion in the immediate postresuscitation period.⁷⁴ Furthermore, a recent case series of four patients undergoing percutaneous dilatational tracheostomy in the intensive care setting illustrated the possible benefits of performing the procedure in combination with ultrasound guidance.⁷⁵ The authors concluded that the use of ultrasound could identify patients unsuitable for the procedure, prevent puncture of aberrant vessels, estimate the distance from the surface of the skin to the trachea, and ensure accurate placement of the needle into the trachea.⁷⁵ While these studies are promising, larger studies are needed to determine the ultimate role of percutaneous dilatational tracheostomy in the emergency setting.⁷⁴ **The cricothyroidotomy remains the procedure of choice for emergency surgical access to the airway.**

ASSESSMENT

Once the airway is established, tracheostomy tube positioning should be confirmed by auscultation, ease of ventilation, and pulse oximetry. Obtain a chest and neck radiograph to confirm tracheostomy tube position and exclude a pneumothorax.

AFTERCARE

Once the airway has been established, inspect the wound to ensure hemostasis. Any clamped vessels or thyroid tissue should be tied.

The skin edges do not need to be closed unless the skin incision was overly zealous. If the skin is reapproximated, close it loosely to avoid the development of subcutaneous emphysema. Secure the tracheostomy tube with umbilical tape wrapped around the neck. Suture the flange of the tracheostomy tube to the skin using 3-0 silk as an additional safeguard (**Figure 33-18**). If the wound is oozing, place gauze between the skin and the tracheostomy tube.

Special care should be taken to protect the artificial airway. Suction the lumen frequently and as necessary to prevent obstruction from blood or secretions. Administer humidified oxygen through the tube to prevent dried and inspissated secretions from occluding the tracheostomy tube.

COMPLICATIONS

An elective tracheostomy is a relatively basic and common surgical procedure. Despite this, it has an unusually high complication rate. Authors report widely different morbidity rates, perhaps determined in part by the clinical settings if not their own biases. Reported morbidity ranges from 6% to 58%, with procedures done emergently having the highest rates of complications.^{22,23,25,36} However discomfiting these numbers may be, the risk is certainly acceptable in the face of an unstable airway in a dying patient.

Complications from a tracheostomy can be divided into immediate operative complications, postoperative complications, and delayed complications. A summary of reported complications are listed in **Table 33-4**. **It cannot be stressed enough that the best way**

FIGURE 33-18. The tracheostomy tube is secured in place with umbilical tape ("tracheal tie") and then sutured.

TABLE 33-4 Complications of Tracheostomies

Immediate	Delayed	Postoperative
Air embolism	Accidental decannulation	Accidental decannulation
Aortic arch rupture	Delayed wound problems	Aspiration
Apnea	Excess granulation tissue	Delayed hemorrhage
Cardiac arrest	Persistent stoma	Delayed wound problems
Cardiac dysrhythmias	Fused vocal cords	Excess granulation tissue
Cartilage injury	Hemorrhage	Persistent stoma
Cricoid	Infection	Disrupted tract
Trachea	Mediastinitis	Displaced tube
Tracheal rings	Pneumonia	Infection
Cuff rupture	Sternoclavicular joint	Mediastinitis
Damage to surrounding structures	Stoma	Pneumonia
Anterior jugular vein	Tracheitis	Sternoclavicular joint
Common carotid artery	Wound	Stoma
Esophagus	Subglottic stenosis	Tracheitis
Internal jugular vein	Tracheal stenosis	Wound
Pleura	Tracheal tube obstruction	Mediastinal emphysema
Pneumothorax	Tracheal tube cuff rupture	Obstructed tube by mucus plug
Pneumomediastinum	Tracheoesophageal fistula	Subcutaneous emphysema
Posterior tracheal perforation	Tracheoinnominate artery fistula	Tracheal tube cuff rupture
Recurrent laryngeal nerve	Tracheomalacia	Voice changes
Subcutaneous emphysema	Voice changes	
Voice changes

to avoid complications is to avert the need for a tracheostomy.

Under emergent circumstances, a variety of things can and do go wrong. It is best if one has thought about these possibilities, considered alternative strategies for airway management, and sought assistance from surgical colleagues. A more detailed discussion regarding chronic complications is found in Chapter 34.

The most common problem with a hastily performed tracheostomy is hemorrhage. Most bleeding can be controlled with the application of direct pressure. An assistant may be invaluable in providing sufficient control until the airway is established. **The search for a bleeding source during the procedure will waste valuable time and can usually wait until the airway is established.** The best way to avoid this difficulty is strict hemostasis during the procedure and being careful to avoid the transection of any blood vessels. The next most likely problem is inadvertent injury to adjacent structures. **Injury to adjacent structures is avoided by remaining strictly in the midline, positioning the patient properly, and using a tracheal hook.** Additional problems that can be encountered include the creation of a false passage. This should not occur if the operator has visualized the trachea and remained in the midline. In pediatric patients, pneumomediastinum is one of the most frequent early complications of a tracheostomy.⁸⁷

The Emergency Physician should be cautious not to adopt methods for tracheostomies learned from elective procedures performed in the Operating Room under controlled circumstances. **The emergent tracheostomy must be carried out with the simplest, fastest, and most straightforward technique possible.** Tracheostomies done under elective conditions may use rescue stay sutures and more elaborate tracheal incisions. The added benefits of these features do not offset the additional time required to perform them.

Any physician who cares for patients under emergency circumstances should think through the clinical scenarios in which an emergent tracheostomy may be necessary. Expertise in surgical airway techniques should first be obtained in a laboratory setting. Unless one is poised to respond with a plan of action for the

emergent airway and prepared with the necessary surgical skills, such situations create chaos and all too often end in disaster.

SUMMARY

A well-trained Emergency Physician must be prepared for any kind of airway emergency and should be skilled in a variety of approaches. Optimal airway management begins with optimal medical management of the patient, including the early identification of possible airway compromise and aggressive preventive treatment. Many airway problems can be averted with anticipatory action. In the armamentarium of airway procedures, a tracheostomy will be and should be a rare solution. The Emergency Physician who is knowledgeable about and comfortable with alternative airway techniques, including surgical access, will be prepared to act decisively yet appropriately upon encountering a challenging airway crisis. While a cricothyroidotomy is the surgical airway procedure of choice, a tracheostomy should be considered for laryngeal injuries with airway disruption or when all other methods have failed.

In the future, an automatic device may make emergent tracheotomies faster and safer.⁸⁸ Researchers in Madrid have designed a device and patented it. The device identifies the trachea and makes a clean incision. It does this by locating the correct location, adjusting the needle preload, making the incision, dilating the incision, and maintaining the airway.

Tracheostomy Care

H. Gene Hern Jr and Julie K. Oliva

INTRODUCTION

Tracheostomy care and management of tracheostomy complications are tremendously important to the Emergency Physician. Rapid assessment and understanding of tracheostomies and their potential complications can be lifesaving in the critically ill and tracheostomy-dependent patient.

Tracheostomies have been performed since ancient times but have been perfected in the last few centuries. A Greek physician named Asclepiades of Bismuth was the first credited in 100 BC with performing a successful tracheostomy.¹ Two of the four physicians summoned to President George Washington's deathbed were said to have argued for tracheostomy as his only means of survival. Trousseau reported successful tracheostomies in more than 2000 cases of upper airway obstruction secondary to diphtheria in the 1800s.² Chevalier Jackson perfected the tracheostomy technique and reduced the operative mortality from 25% to less than 1% in the 20th century.³ This is roughly what it remains today.

The important aspects of tracheostomy care include the assessment of respiratory distress in the tracheostomy patient, proper suctioning techniques, and assessment and evaluation of possible complications arising from the tracheostomy or its placement. Tracheostomy care will be divided into routine care and emergent care.

ANATOMY AND PATHOPHYSIOLOGY

The trachea is a fibromuscular tube with approximately 16 to 20 cartilaginous arches extending from the cricoid cartilage to the division at the carina into right and left mainstem bronchi (**Figure 33-4**). The surface of the tracheal mucosa is covered in respiratory epithelium. This epithelium is responsible for tracheal secretion, mucociliary "elevator" movement of secretions and debris, and humidification. The remaining part of the upper respiratory tract bypassed by the tracheostomy plays a major role in warming and humidifying inspired air.

The terms *tracheostomy* and *tracheotomy* are widely interchanged in current parlance. Tracheotomy refers to the actual incision through the skin to the trachea, which is then kept open by a tracheotomy tube. A tracheostomy refers to the procedure in which the tracheal opening is sutured to the skin incision. This creates a more permanent orifice. The term *tracheostomy* will be used for the remaining sections of this chapter.

A tracheostomy is created by an incision at the level of the second or third tracheal rings. An incision is made into the trachea after the subcutaneous tissue is dissected and anatomic structures identified. A hook is inserted into the incision and used to stabilize the trachea while a tube is placed into the trachea. The trachea is secured to the overlying skin and the tube is secured in place. Further details can be found in Chapter 33.

TRACHEOSTOMY TUBES

Tracheostomy tubes vary in their composition, angles, and types and the presence or absence of a cuff (**Tables 34-1, 34-2, and 34-3**). The basic tube consists of an outer cannula and an inner cannula (**Figure 34-1**). The size of the tracheostomy tube is usually defined by its inner diameter. The outer cannula is the more permanent fixture in the tracheostomy. The inner cannula is a low-profile tube that inserts into the outer cannula. It can easily be removed and replaced. The inner and outer cannulas contain a locking mechanism by which the inner cannula is secured into the outer cannula. The proximal end of the inner cannula contains a standard 15 mm connector that allows direct connections to a ventilator or bag-valve device. The tracheostomy tube is available in fenestrated and non-fenestrated versions (**Figure 34-2**).

Pediatric tracheostomy tubes have a much smaller inner diameter and do not accommodate inner cannulas (**Figure 34-3**). They require more frequent suctioning and changing since pediatric tracheostomy tubes are not made with an inner cannula.

TABLE 34-2 Some of the Commonly Used Shiley XLT Extra-Length Tracheostomy Tubes

ID (mm)	Distal extension tubes		OD (mm)	Proximal extension tubes	
	OD (mm)	Length (mm)		OD (mm)	Length (mm)
5.0	9.6	90 (48 distal, 37 radial, 5 proximal)	9.6	90 (33 distal, 37 radial, 20 proximal)	
6.0	11.0	95 (49 distal, 38 radial, 8 proximal)	11.0	95 (34 distal, 38 radial, 23 proximal)	
7.0	12.3	100 (49 distal, 39 radial, 12 proximal)	12.3	100 (34 distal, 39 radial, 27 proximal)	
8.0	13.3	105 (50 distal, 40 radial, 15 proximal)	13.3	105 (35 distal, 40 radial, 30 proximal)	

ID, inner diameter; OD, outer diameter.

Tracheostomy tubes are manufactured with and without cuffs (**Figure 34-4**). These high-volume, low-pressure cuffs can be used for extended periods with minimal mucosal injury. **Cuffed tubes are used in patients who are dependent on mechanical ventilation or have a history of aspiration.**

Obturator is solid devices that aid in the smooth insertion of the tracheostomy tube (**Figures 34-3 and 34-5**). An obturator will totally occlude the outer cannula and extend a few millimeters beyond the distal end when placed inside the outer cannula. The smooth tip of the obturator allows the outer cannula to be inserted with minimal effort and prevents the edges of the cannula from getting caught and damaging tissue. The obturator is removed and replaced with a low-profile inner cannula once the outer cannula has been inserted.

ROUTINE CARE

The routine care of the patient with a tracheostomy includes cleaning of the tube, humidification of incoming air, and suctioning of the tracheostomy. Inspired air that bypasses the upper respiratory tract in patients with tracheostomies is not as warm or humidified as air inspired through the nose or mouth. The mucociliary “elevator” becomes impaired when cold dry air is inspired into the trachea and results in thicker secretions. It is important to warm and humidify the inspired air for the patient with a tracheostomy who is in the immediate postoperative period, who is dependent on mechanical ventilation, or who has a history of thick secretions.^{4,5}

Care of the tracheostomy must include ensuring adequate cleanliness of the tube. Cleanse the skin site with diluted hydrogen peroxide at a 50% concentration.⁵ This can be applied to cotton-tipped swabs or other similar absorbent devices and then to the tube.⁵ Keep the skin surrounding the tracheostomy dry between cleanings with tracheal bandages or gauze sponges. **Note the underlying skin**

**FIGURE 34-1.** The tracheostomy tube consists of an outer cannula (*left*) and an inner cannula (*middle*). The inner cannula inserts and locks into the outer cannula (*right*).

condition. Erythematous or macerated skin can become eroded or infected. Use and teach the patient or their caregiver proper skin-care techniques to ensure skin viability. **Ensure that the tracheal bandages or tape used to secure the tracheostomy in place is not so tight that skin perfusion is compromised.** A good rule of thumb is to have two finger breadths of laxity between the skin and the securing ties.⁶

SUCTIONING

Suction the tracheostomy when there are thick and tenacious secretions at the tracheostomy lumen or when the patient is having difficulty clearing secretions.⁷ Suctioning through the tracheostomy will eliminate debris and infectious agents, improve oxygenation, and prevent atelectasis. Other indications for suctioning include suspicion of airway obstruction, diminished or coarse breath sounds, unexplained decreases in oxygen saturation levels, increased airway pressures, or before and after the tracheostomy tube is changed.⁸ Do not suction as part of “routine care” when there are few secretions or if the patient is adequately able to generate enough force to clear the secretions.⁹ The suctioning of tracheostomies is often essential to proper pulmonary toilet.⁷ **Suctioning can be hazardous.** Known complications from tracheal suctioning include arrhythmias, atelectasis, cardiac arrest, hypotension, hypoxia, infections, tracheal mucosal damage, and vagus stimulation.^{8,10}

Suctioning can be very frightening to the patient and must be done with some expediency and professionalism.⁷ These patients’ anxiety levels are quite high as their ability to breathe may be compromised by secretions. The patient may be hypoxic and may have a decreased ability to communicate freely at baseline.⁵

EQUIPMENT

- Protective clothing (i.e., disposable gowns, gloves, face shields, goggles, shoe covers)
- Bag-valve device
- Flexible multi-eyed suction catheter, less than half the inner cannula diameter
- Saline bullets
- Continuous wall suction
- Pressure regulator to maintain suction pressure

(Photo courtesy of Kapitex Healthcare.) **C.** A fenestrated versus a nonfenestrated tube. (Used from Cancer Research UK, commons.wikimedia.org.)

PATIENT PREPARATION

Place the patient in an upright or semirecumbent position. Hyperextend the patient's neck if possible. Preoxygenate the patient with 100% oxygen prior to suctioning. **Hypoxia is a common complication of suctioning and can be virtually eliminated with proper preoxygenation.** Proper preoxygenation often prevents cardiac arrhythmias from occurring during suctioning.¹⁰ Pretreatment with atropine in neonates and children has been suggested to minimize bradycardic episodes.¹¹

It has been debated which technique of preoxygenation is best. Options include hand ventilation with a bag-valve device for five to

eight breaths, hyperventilation with 100% O₂ via a nonrebreathing mask, or hyperventilation with 100% O₂ via a ventilator. The advantage of hand ventilation is that there is faster delivery of oxygen to the lungs rather than waiting for the higher percentage of oxygen to bleed down the ventilator tubing into the lungs. **Maintaining tidal volumes and positive end-expiratory pressure may be more important.** The bag-valve device may result in decreased cardiac output and hypotension secondary to increased intrathoracic pressures.⁸ The method of preoxygenation is up to the Emergency Physician's discretion.

FIGURE 34-3. The pediatric tracheostomy tube and its obturator.

FIGURE 34-4. Tracheostomy tubes may be uncuffed (left) or cuffed (middle). The inflated cuff is a high-volume, low-pressure system (right).

FIGURE 34-5. The obturator is a solid device (*left*) that inserts into the proximal end of the outer cannula and projects from the distal end of the outer cannula (*right*).

TECHNIQUE

Assemble and prepare the equipment. Set the pressure regulator to 60 to 80 mmHg for infants, 80 to 100 mmHg for children, and 100 to 120 mmHg for adolescents and adults. **Higher pressures may cause injury to the tracheal mucosa.** Choose a suction catheter one-half the diameter of the tracheostomy tube. The catheter has an open valve that must be covered to apply suction through the tip of the catheter. Apply cardiac monitoring and pulse oximetry to the patient prior to suctioning if time permits.

Perform the procedure using a clean technique. Wash your hands and apply sterile gloves. The use of a face mask, eye protection, and a gown is highly recommended. The insertion of the suction catheter often induces the patient's cough reflex. Proper protective clothing will prevent the Emergency Physician from being exposed to respiratory secretions.

Gently insert the suction catheter into the trachea (**Figure 34-6**). Advance it approximately 8 to 10 cm until the tip is at the level of the carina. **Do not ever apply suction pressure during insertion of the suction catheter.** Withdraw the catheter approximately 2 to 3 cm and apply suction by placing a finger over the catheter's open valve.¹² **Continue to apply suction as the catheter is simultaneously rotated and withdrawn.** This technique will limit the amount of mucosal damage from the suction catheter. The mucosal surface will invaginate into the holes in the suction catheter tip. The resulting trauma may cause bleeding or erosion of the tracheal mucosal surface if the catheter is not being withdrawn when suction is applied.⁹

Suction the airway for no more than 10 to 15 seconds.⁹ This will ensure that the patient experiences a minimal amount of hypoxia. Preoxygenation with 100% oxygen must precede each suctioning episode if the suctioning must be repeated.

The standard use of saline to loosen secretions is somewhat controversial. Some authors have suggested that saline is used to break up thick and tenacious sputum and mucus.¹¹ There is little support for this assertion. It has been shown that saline instillation increases the cough reflex and stimulates a cough response, which may increase mucus clearance. Others have noted that little saline is recovered with suctioning and that saline itself may cause a gradual decrease in oxygen saturation.⁸ The instillation of saline into the tracheostomy cannot be recommended.

FIGURE 34-6. Insertion of a suction catheter. The vent is uncovered during insertion to prevent tracheal mucosal injury.

EMERGENT CARE

Immediate attention must be given when a patient with a tracheostomy presents to the Emergency Department complaining of shortness of breath or respiratory distress. Obstruction and hypoxia are frequent causes of morbidity in this patient population. What follows is a discussion of the algorithm for airway obstruction and respiratory distress in the patient with a tracheostomy.¹⁰

EQUIPMENT

- Protective clothing (i.e., disposable gowns, gloves, face shields, goggles, shoe covers)
- Bag-valve-mask device
- Flexible multi-eyed suction catheter less than half the inner cannula diameter
- Saline bullets
- Continuous wall suction
- Suction pressure regulator
- Continuous electrocardiogram monitor
- Pulse oximetry
- Tracheal tubes of various sizes, at least the current size of the tube and one smaller
- Water-soluble lubricant
- Tracheal airway kit (e.g., dilator, forceps, and hook)
- Endotracheal tubes
- Laryngoscope handle and blades
- Access to advanced airway equipment, including a fiberoptic scope

PATIENT PREPARATION

The evaluation of any patient with a tracheostomy who is in respiratory distress begins with placing the patient in a room capable of advanced airway management. Place the patient on 100% oxygen and obtain intravenous access, cardiac monitoring, and continuous pulse oximetry. Equipment should be readily available and accessible. This includes endotracheal and tracheostomy tubes of various sizes as well as a laryngoscope and laryngoscope blades.

The Emergency Physician must evaluate the type of tracheostomy tube present. Recognition of the type of tube will aid in the evaluation of possible complications and the management of the respiratory distress. The entire tracheostomy tube may have to be removed for further cleaning after suctioning is performed if the tube has no inner cannula (e.g., pediatric tubes). The patient's respiratory distress may be due to aspiration of secretions or gastric contents if the tracheostomy tube has no cuff.

TECHNIQUE

Inspect the tracheostomy tube for obvious signs of obstruction.

The degree of obstruction will increase exponentially as the cross-sectional diameter of the tracheostomy tube decreases. The amount of force required to create airflow through the tube increases dramatically as aspirated material, blood, or dried secretions gather in the inner cannula. Secretions may act as a ball-valve mechanism and allow air to move inward but not outward.

Remove an obvious obstruction or foreign body if it is visible at the tracheostomy tube opening. The Emergency Physician must then suction the patient through the inner cannula using the technique described above. **Keep in mind the importance of preoxygenation.** Remove the inner cannula if this does not adequately relieve the patient's respiratory distress. Inspect it for dried secretions and clean it later if necessary. Suction the patient through the outer cannula. The outer cannula may need to be removed if no diminution of symptoms is noted.

Before removing the outer cannula, it is important to have all the necessary equipment to replace it at the bedside. If the outer cannula has a cuff, deflate it. Remove the outer cannula with a smooth circular motion. Inspect it for a foreign body and dried secretions. The outer cannula may be cleaned and replaced or may be replaced with an entirely new tracheostomy tube. The Emergency Physician may elect to use a fiberoptic scope or red rubber catheter to aid in tube placement. Each of these devices allows the tracheostomy tube to be placed over it and guided into the tracheal lumen.

Remove a relatively new tracheostomy tube (i.e., less than 4 weeks old) over a red rubber catheter (**Figure 34-7**). This will ensure that the tracheostomy tube is inserted into the trachea and not a false passage (**Figure 34-8**). Lubricate the red rubber catheter. Insert the catheter through the outer cannula and into the trachea (**Figure 34-7A**). Advance the catheter 8 or 9 cm. While holding the catheter securely, remove the outer cannula over the catheter (**Figure 34-7B**). Lubricate a new outer cannula. Insert the outer cannula over the catheter and gently advance it into the trachea (**Figure 34-7C**). Remove the catheter and insert the inner cannula into the outer cannula.

A suction catheter can be used as an alternative to a red rubber catheter. **Attach the suction catheter to an oxygen source.** Lubricate the end of the suction tubing. Advance an outer cannula over the distal end of the suction tubing. Insert the suction catheter into the tracheostomy to a depth of 8 or 9 cm. Place a finger over the open valve of the suction catheter to provide oxygen to the patient through the catheter. **This will prevent the patient from becoming hypoxemic during the procedure.** Advance the outer cannula over the catheter and into the trachea. Remove the suction catheter and insert the inner cannula into the outer cannula.

The tracheostomy tube can be replaced manually if no assist device is used (**Figure 34-9**). Lubricate the obturator and insert it into the outer cannula. Inflate the cuff and check its integrity. Deflate the cuff. Lubricate the outer cannula liberally. Place the tip of the

FIGURE 34-7. Removal of the outer cannula over a catheter. **A.** The catheter is inserted through the outer cannula to a depth of 8 to 9 cm. **B.** The outer cannula has been removed over the catheter. **C.** The new outer cannula is inserted over the catheter and into the trachea.

FIGURE 34-8. CT scan image through the torso demonstrating the tracheostomy tube in a false passage outside of the trachea.

obturator perpendicular to the patient's neck and insert it with a semicircular motion (**Figure 34-9A**). Continue advancing the outer cannula with a semicircular motion as it curves into the trachea (**Figure 34-9B**). Remove the obturator and insert the inner cannula into the outer cannula. Begin ventilation of the patient if necessary.

Repeat the procedure with a tracheostomy tube one size smaller if the new tracheostomy tube will not advance into the trachea. **Do not force the tube as it can create a false passage (Figure 34-8).** Attempt to insert an uncuffed tube if it still will not advance. Alternatively, insert the tracheostomy tube over a catheter (**Figure 34-10**). Lubricate a red rubber catheter (or oxygen catheter) and insert it 8 or 9 cm through the tracheostomy (**Figure 34-10A**). Insert a lubricated outer cannula over the catheter and into the trachea (**Figure 34-10B**). Remove the catheter and insert the inner cannula. As a last resort, a tracheostomy hook and Trousseau dilator can be used to lift and open the tracheostomy site to allow the insertion of a tracheostomy tube. Sometimes a tracheostomy tube cannot

be passed into the trachea and the patient cannot be oxygenated or ventilated. There is the fear the airway will be lost. Attempt endotracheal intubation.⁴ The management is summarized in **Figure 34-11**.

DISLODGEEMENT OF THE TRACHEOSTOMY

The tracheostomy tube can accidentally be dislodged.¹³ This can result in respiratory distress. Predisposing factors to tracheostomy tube displacement include agitation, coughing, edema of the area, loose ties, and placement problems. Management depends on the timing of the dislodgement relative to the surgery to make the tracheostomy (**Figures 34-12, 34-13, and 34-14**). It is divided into fresh sites (i.e., < 7 days), relatively fresh sites (i.e., 7 to 30 days), and "old" sites (i.e., > 30 days) from the time of surgery. Much of the management has already been discussed above.

ASSESSMENT

The adequacy of airway maneuvers in the patient with a tracheostomy resides in the patient's response to the interventions. Secure the tracheostomy tube if the patient's pulse oximetry and heart rate return to baseline and the patient appears more comfortable. Take care to ensure adequate skin care beneath the tracheostomy tube site.

Further causes of respiratory distress must be evaluated if a patient remains in respiratory distress despite all appropriate actions. Obtain a chest radiograph. Consult a Pulmonologist for fiberoptic bronchoscopy to evaluate the patient for mucus plugging or foreign-body aspiration. Do not forget to consider other causes of respiratory distress in the patient with a tracheostomy (e.g., heart failure, myocardial infarction, pneumonia, pneumothorax, and pulmonary embolus.)

AFTERCARE

Observe the patient to ensure the stability of the airway. Further suctioning can be performed as required during this time. Educate the patient, their family, and their caregiver about preventive measures regarding tracheostomy care.

FIGURE 34-9. Manual insertion of a tracheostomy tube. **A.** It is positioned 90° to the tracheostomy site and advanced with a semicircular motion (arrow). **B.** The system continues to be advanced, following the curve of the tube, until the flange is against the skin.

FIGURE 34-10. Insertion of the tracheostomy tube over a catheter. **A.** Insert the catheter through the tracheostomy to a depth of 8 to 9 cm. **B.** Advance the outer cannula over the catheter.

Evaluate the patient for further conditions that may preclude them from being discharged once the patient's respiratory distress has been addressed. Were there just some dried secretions in the inner cannula? Does the patient have a new source of secretions

(e.g., bacterial pneumonia) that could not be managed at home? Are the caregivers at home knowledgeable about the tracheostomy and trained to deal with complications? Admit the patient if there is any question about the patient's ability to deal with further episodes of

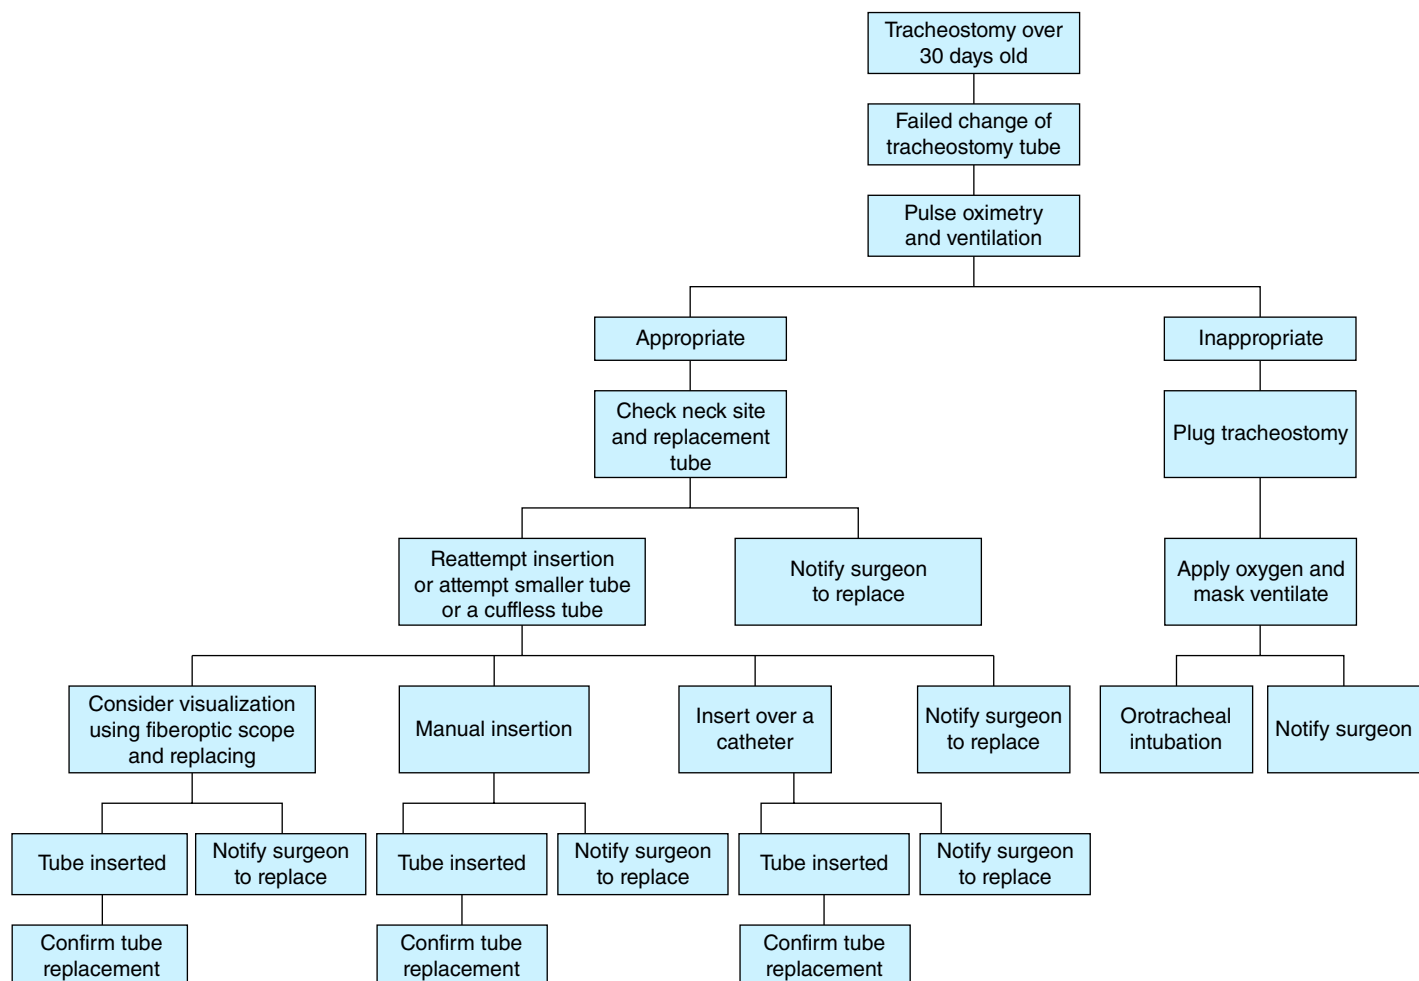

FIGURE 34-11. Algorithm for the steps with a failed tracheal tube replacement.

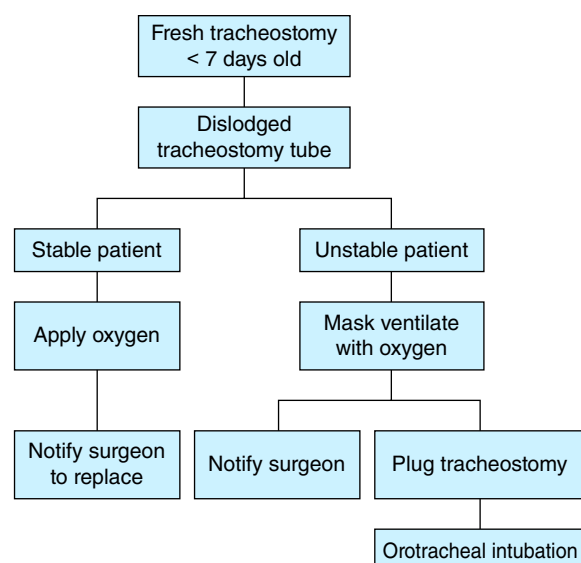

FIGURE 34-12. Algorithm for a dislodged tracheostomy tube < 7 days old.

respiratory compromise. The patient may require skilled home care or a skilled nursing facility to fully care for the tracheostomy.

COMPLICATIONS OF THE TRACHEOSTOMY

Respiratory compromise from plugging of the tracheostomy with secretions may bring the patient to the Emergency Department. Other complications of the tracheostomy may cause the patient to present to the Emergency Department.¹⁴ One retrospective review over a 7-year period showed that 33% of patients presented with dislodged tracheal tubes, 30% presented with infection (one-quarter of these had cellulitis around the tracheostomy; the rest had bronchitis or pneumonia), 18% had plugged tracheal tubes, 11% had bleeding, 5% had tracheal or stomal stenosis, and 3% had a pneumothorax.²

BLEEDING

Bleeding is a significant concern in the patient with a tracheostomy.¹³ Bleeding at the site of a recent tracheostomy may be a frequent

complication. It can be extremely serious. Bleeding can arise from granulation tissue, venous sources, or arterial sources including the great vessels. Tracheoinnominate fistulas are quite rare. They occur in less than 2% of cases, but they carry a mortality rate of up to 50%.¹¹ They may present as the classic “exsanguinating bleed” but often present with a less impressive sentinel bleed. **Any bleeding of more than a few milliliters of blood should raise concern for a possible fistula of the innominate artery. Prompt critical resuscitation measures and emergent consultation with a Vascular Surgeon and Otolaryngologist are required. Definitive management is surgical.** Techniques for temporarily controlling bleeding from the innominate artery include local digital pressure, hyperinflation of the tracheostomy tube cuff, and traction on the tracheostomy tube. An alternative method is to deflate the tracheostomy tube cuff, reposition the cuff at the bleeding site, and then reinflate or hyperinflate the cuff. **Do not remove the tracheostomy tube until the airway is secured by another means from above (e.g., orally or nasally) when bleeding occurs.**

FREE AIR

Pneumothoraces, pneumomediastinum, and subcutaneous air occur in a small number of patients.¹¹ Pediatric patients are at a higher risk as the dome of the pleura in a child is closer to the site of the operation. As patients “fight” a ventilator or attempt to inspire against an obstructed airway, they can generate tremendous negative inspiratory pressures. This can result in the dissection of air between the tissue planes and into the thoracic cavity. Small pneumothoraces and pneumomediastinum can be observed as they will most likely resorb with no further complications. A large pneumothorax will require drainage. **The possibility of a tension pneumothorax must always be considered in patients with tracheostomies and respiratory distress or hypotension.**

GRANULOMAS

Tracheal wall granulomas can develop at the tracheostomy site or near the tip of the tracheostomy tube. They are formed in response to mechanical trauma to the mucosa. Granulomas are sometimes a source of bleeding. Direct pressure or cautery may be required for hemostasis. Small granulomas are often observed. Large or symptomatic granulomas require excision.

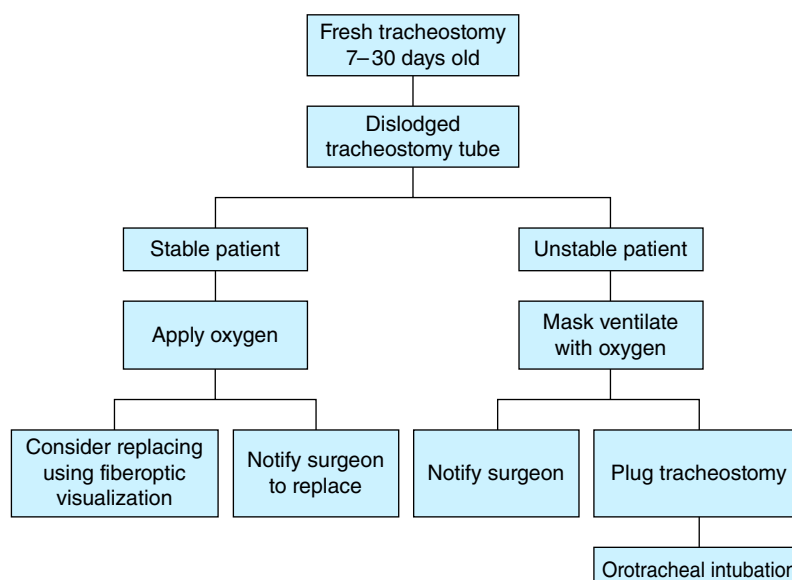

FIGURE 34-13. Algorithm for a dislodged tracheostomy tube 7 to 30 days old.

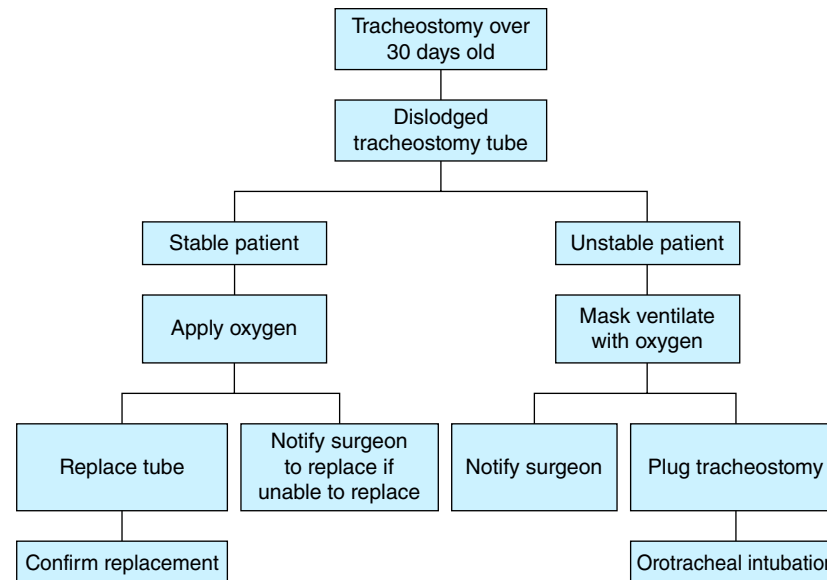

FIGURE 34-14. Algorithm for a dislodged tracheostomy tube > 30 days old.

INFECTIONS

Tracheostomy-related infections can present at any time. Stoma infections are considered local skin infections. Base antibiotic treatment on potential pathogens and local antibiotic resistance patterns. Tracheitis may be bacterial or viral in origin. Common bacterial etiologies include *Staphylococcus aureus*, group A *Streptococcus*, and *Haemophilus influenzae*. Base the determination of a bacterial infection versus colonization on clinical findings and culture results. Management of tracheitis includes broad-spectrum antibiotics for common pathogens, maintenance of a patent airway through suctioning, and possible bronchoscopy.

LARYNGOTRACHEAL STENOSIS

Laryngotracheal stenosis is a complication of long-term endotracheal intubation or direct tissue trauma from the tracheostomy. The tracheal tissues become irritated from the tracheostomy tube. This results in tissue edema that leads to erosions into the mucosa, ulcerations, and eventually scar tissue. Treatment involves surgery to remove the scar tissue and to create an artificial airway to bypass the stenosis.

DEPRESSED SCAR FORMATION

The tracheostomy wound is left open to granulate and heal by secondary intention. This can result in skin atrophy, soft tissue atrophy, and tissue adhesions to the anterior tracheal wall. Scar contracture and a depressed scar can result as the tissue heals. This may result in patient discomfort with head movement or swallowing. Treatment requires surgical scar excision and revision.

SUPRASTOMAL COLLAPSE

Pressure placed on the tracheal cartilages by the tracheostomy tube results in cartilage inflammation, chondritis, and necrosis of the cartilaginous rings. Mild suprastomal collapse usually requires no treatment. Moderate and severe collapse may require a tracheal stent, suturing the anterior trachea to the skin and subcutaneous tissues, or pulling the anterior trachea anteriorly and securing it in place.

TRACHEOESOPHAGEAL FISTULA

A tracheoesophageal fistula is a rare complication of a tracheostomy.¹³ The tracheostomy tube can cause pressure necrosis on the posterior tracheal wall that continues to erode into the esophagus. The result is an open tract between the trachea and the esophagus. Patients often have difficulty eating, aspiration pneumonitis, or respiratory difficulty associated with eating and drinking. Treatment requires surgical management.

TRACHEOMALACIA

Tracheomalacia is the lack of support for the trachea by its cartilaginous rings. It can result from degradation of the cartilaginous tracheal rings from the tracheostomy tube or from a tracheoesophageal fistula. Bronchoscopy is required to assess the severity of the tracheal collapse prior to possible intratracheal stenting.

SUMMARY

Emergency Physicians should be familiar with tracheostomy equipment (e.g., the outer and inner cannulae, obturators, and cuff management). Patients presenting to an Emergency Department may require immediate and critical intervention to resuscitate them. Familiarity with various techniques to evaluate the patient with a tracheostomy should include tracheal suctioning, removal of the inner and outer cannulae, replacement of a tracheostomy tube, and evaluation for other emergent conditions relating to tracheostomies. This includes bleeding, infection, and pneumothorax at the very minimum. The Emergency Physician should be mindful of other conditions of the esophagus, trachea, or soft tissues that might complicate the care of the patient with a tracheostomy.

Transtracheal Aspiration

Joseph A. Salomone III

INTRODUCTION

Transtracheal aspiration is a technique for the collection of lower respiratory tract and bronchial secretions for laboratory evaluation and culture.^{1,2} This technique is useful when standard sputum collection has not provided adequate material or determination of the infective agent(s). Specimens collected by this technique are free of contamination from nasal, oral, and pharyngeal secretions. This technique was first described in 1959.³ Several modifications to the original technique have been made.⁴⁻⁷ This technique may be more properly named transcricothyroid membrane aspiration. It is not used as much as in the past since the development of bronchoscopy. Despite this, it is safe, takes less preparation, takes less personnel, takes less equipment, and is much less expensive when compared to bronchoscopy.

ANATOMY AND PATHOPHYSIOLOGY

The most superficial portion of the cervical airway begins at the inferior thyroid cartilage and extends inferiorly to the thyroid isthmus (Figure 35-1). The inferior border of the thyroid cartilage is attached

to the cricoid cartilage by the cricothyroid ligament. This is formed by a thicker central conus elasticus and laterally by thinner ligaments that are covered by the cricothyroid muscles (Figure 35-1B). The internal surface is covered by the mucous membrane of the larynx. Collectively, this is often referred to as the cricothyroid membrane or cricovocal membrane. The paired cricothyroid arteries cross from lateral to medial to form an arch that anteriorly crosses the upper one-third of the cricothyroid membrane. The pyramidal lobe of the thyroid occasionally extends superiorly to this level.

INDICATIONS

Transtracheal aspiration is indicated for the collection of tracheo-bronchial secretions for laboratory evaluation. Often, previous attempts to collect standard coughed and expectorated sputum samples have failed to yield adequate samples or reveal the etiology of a pulmonary infection. Patients who do not appear to be responding to the appropriate antibiotic regimen that was indicated by evaluation and culture of sputum samples may benefit from this technique to better determine the pathogen(s). This is particularly true in cases of atypical or mixed flora, as in suspected aspiration pneumonias, where this technique may yield superior culture results when compared to sputum samples.⁸

CONTRAINDICATIONS

Patients who are unable to cooperate with or tolerate the required positioning should not be selected for this technique.⁹ Agitated patients requiring sedation that may affect respiratory effort should be avoided. Traumatically injured patients should have the cervical spine cleared for possible injury prior to performing the procedure. Patients with known or suspected blood dyscrasias (e.g., abnormal platelet counts, elevated prothrombin or partial thromboplastin times) should not be subjected to this technique due to the increased risk of tracheal hemorrhage. The Emergency Physician must be able to easily identify the patient's anatomic landmarks, including the thyroid and cricoid cartilages and the intervening cricothyroid membrane. Patients with abnormal or distorted anatomy should be excluded. Patients who are endotracheally intubated or have a tracheostomy do not require this procedure.

EQUIPMENT

- Sterile gown, gloves, and mask
- Pillow or padding for shoulders

FIGURE 35-1. Anatomy of the airway structures of the neck. **A.** Topographic anatomy. **B.** The cartilaginous structures.

- Povidone iodine solution or chlorhexidine solution
- Sterile gauze squares
- Normal saline solution, sterile and preservative-free
- Local anesthetic solution, 3 mL (1% lidocaine HCl)
- 3 mL syringes
- 30 mL syringe
- 25 to 27 gauge needles, ½ inch long
- 18 to 22 gauge catheter-through-the-needle, 3 inches long
- 18 to 22 gauge catheter-over-the-needle, 3 inches long
- 18 to 19 gauge needles, 1½ inches long
- Pulse oximeter
- Cardiac monitor
- Sterile specimen container
- Bandage, 1 inch wide
- Sterile drapes or towels
- Resuscitation equipment including emergent airway management supplies

PATIENT PREPARATION

Explain the procedure, its risks, and its benefits to the patient and/or their representative. Obtain an informed consent. Place the patient on cardiac monitoring and continuous pulse oximetry. Administer supplemental oxygen and establish intravenous access.

Sedation is not generally required. A small dose of midazolam (1 to 5 mg IV) may be used, if appropriate, for light sedation. Deep sedation should be avoided, as it may compromise respiratory effort and increase the risk of aspiration of gastric contents.

Place the patient supine in bed. Place a pillow or appropriate padding under the patient's shoulders and upper back to allow for comfortable hyperextension of the neck. Identify by palpation the thyroid cartilage, laryngeal prominence (Adam's apple), cricoid cartilage, and cricothyroid membrane. These are the anatomic landmarks that will be used to identify the proper site for performing the procedure.

TECHNIQUE

CATHETER-THROUGH-THE-NEEDLE TECHNIQUE

The operator should follow universal precautions with the use of a mask, eye protection, a sterile gown, and sterile gloves. Using sterile technique, prepare the equipment. Draw 3 to 5 mL of sterile and preservative-free normal saline solution into a 30 mL syringe with a sterile needle. Attach an appropriately sized needle from a catheter-through-the-needle set (18 to 20 gauge for an adult, 20 to 22 gauge for a child) to a 3 mL syringe. An alternative technique is to draw up 1 to 2 mL of sterile saline into the syringe before attaching the catheter-through-the-needle. Draw up 1 to 3 mL of local anesthetic solution into a 3 mL syringe armed with a 25 to 27 gauge needle.

Position the patient as noted above. Using sterile technique, prepare the neck. Clean the anterior neck of any dirt and debris. Apply povidone iodine or chlorhexidine solution and allow it to dry. Place sterile towels or a sterile drape to isolate the anterior neck. Palpate the anterior neck and reidentify the thyroid cartilage, laryngeal prominence, cricoid cartilage, and cricothyroid membrane. Leave the nondominant index finger over the cricothyroid membrane for reference.

Apply a small subcutaneous wheal of local anesthetic solution below the skin at the anterior midpoint of the cricothyroid

FIGURE 35-2. A subcutaneous wheal of local anesthetic solution is placed over the middle of the cricothyroid membrane.

membrane (**Figure 35-2**). Inject 0.5 to 1.0 mL of local anesthetic solution into the subcutaneous tissues down to the level of the cricothyroid membrane, taking care not to distort the anatomy. Reidentify the cricothyroid membrane by palpation. Insert the needle on the syringe, directed caudally and at a 30° to 45° angle to the skin (**Figure 35-3**). Continue to advance the needle while applying negative pressure to the syringe (**Figure 35-3A**). Stop advancing the needle when air is aspirated into the syringe. This signifies that the needle is inside the trachea. If using a saline-filled syringe, air bubbles will be clearly visible within the saline. Hold the needle securely and remove the syringe. Insert the catheter through the needle (**Figure 35-3B**). While holding the catheter securely, withdraw the needle until the tip has exited the skin of the neck (**Figure 35-3C**). **Place the needle guard over the needle.** This will prevent shearing off of the catheter. Apply the 30 mL syringe containing saline to the catheter (**Figure 35-3C**).

Ask the patient to cough if they are not already doing so. Aspirate with the 30 mL syringe as the patient coughs. If no specimen is obtained, instill the sterile saline. Once again, ask the patient to cough if not stimulated by the saline. Aspirate until a specimen is acquired. An alternative to using a large syringe for aspiration is the use of low wall suction and a Lukens tube or similar trap device to collect the specimen.

Remove the catheter, needle, and syringe as one unit. Hold direct pressure on the puncture site for 3 to 5 minutes. Apply a bandage or sterile dressing to the puncture site. Place the specimen in a sterile container and have it transported to the laboratory.

Many Emergency Physicians are reluctant to use the catheter-through-the-needle system because there is the possibility of shearing off the catheter within the trachea. **This can be prevented by applying the needle guard over the needle immediately after it is withdrawn from the skin.**

CATHETER-OVER-THE-NEEDLE TECHNIQUE

The more commonly used technique is to use a catheter-over-the-needle (angiocatheter) system (**Figure 35-4**). The operator should

FIGURE 35-3. The transtracheal aspiration technique with a catheter-through-the-needle system. **A.** The needle is inserted through the cricothyroid membrane while negative pressure is applied to the syringe. **B.** The syringe has been removed and the catheter advanced through the needle. **C.** The needle has been withdrawn until its tip exits the skin. A syringe containing saline is attached to the hub of the catheter.

follow universal precautions. Cleanse, prepare, and anesthetize the patient as above.

Using sterile technique, prepare the equipment. Draw 3 to 5 mL of sterile and preservative-free normal saline solution into a 30 mL syringe with a sterile needle. Attach an appropriately sized catheter-over-the-needle (18 to 20 gauge for an adult, 20 to 22 gauge for a child) to a 3 mL syringe. An alternative technique is to draw up 1 to 2 mL of sterile saline into the syringe before attaching the catheter-over-the-needle. Draw up 1 to 3 mL of local anesthetic solution into a 3 mL syringe armed with a 25 to 27 gauge needle.

Reidentify the cricothyroid membrane by palpation. Insert the catheter-over-the-needle on the syringe, directed caudally and at a 30° to 45° angle to the skin (**Figure 35-4A**). Continue to advance the catheter-over-the-needle while applying negative pressure to the syringe. Stop advancing the catheter-over-the-needle as soon as air is aspirated into the syringe. This signifies that the needle is

inside the trachea. If using a saline-filled syringe, air bubbles will be clearly visible within the saline (**Figure 35-4B**). Hold the syringe securely and advance the catheter until its hub is against the skin (**Figure 35-4C**). Remove the needle and syringe. Apply the 30 mL syringe containing saline to the catheter (**Figure 35-4D**).

Ask the patient to cough if they are not already doing so. Aspirate with the 30 mL syringe as the patient coughs. If no specimen is obtained, instill the sterile saline. Once again, ask the patient to cough if not stimulated by the saline. Aspirate until a specimen is acquired. An alternative to using a large syringe for aspiration is the use of low wall suction and a Lukens tube or similar trap device to collect the specimen.

Remove the catheter. Hold direct pressure on the puncture site for 3 to 5 minutes. Apply a bandage or sterile dressing to the puncture site. Place the specimen in a sterile container and have it transported to the laboratory.

FIGURE 35-4. The transtracheal aspiration technique with a catheter-over-the-needle system. **A.** The catheter-over-the-needle is inserted through the cricothyroid membrane. **B.** Negative pressure is applied to the syringe. **C.** The catheter is advanced until its hub is against the skin. **D.** The needle and syringe have been withdrawn. A syringe containing saline is attached to the hub of the catheter.

ASSESSMENT

The patient should be observed for bleeding at the puncture site, the development of subcutaneous emphysema, any changes in sputum production, or hemoptysis. Obtain a chest radiograph immediately after the procedure to look for subcutaneous air and/or a pneumothorax.

AFTERCARE

The patient should remain on continuous pulse oximetry to monitor possible deterioration in respiratory status. Obtain a chest radiograph in 24 hours to look for subcutaneous air and/or a pneumothorax. Any procedure that might stimulate coughing should be avoided for at least 24 hours.

COMPLICATIONS

The complications range from minimal hemoptysis and localized subcutaneous emphysema to massive pulmonary hemorrhage and death.¹⁰⁻¹⁵ There are no major complications if done properly.^{1,2} Minimal hemoptysis was seen in 15% of pediatric patients in one study and commonly in several adult studies. Localized subcutaneous emphysema in the anterior neck occurred in 5% to 18% of patients. There are rare reports of fatal endotracheal hemorrhage, profound coughing with development of massive subcutaneous and mediastinal emphysema, vomiting and aspiration of gastric contents, cardiac dysrhythmias, and sudden cardiac death. There is at least one reported case of fatal gastrointestinal hemorrhage from ruptured esophageal varices and Mallory-Weiss tears following “unrestrainable” coughing.

SUMMARY

Transtacheal aspiration is a useful technique for obtaining uncontaminated specimens for analysis and culture. The procedure is best used in patients who have complicated courses or are failing to respond to appropriate treatment or when there is a high index of suspicion for aspiration pneumonia and more atypical infectious agents.

complications, the assessment of adequacy of therapy, and readiness for liberation.

Normal inspiration is performed by the expansion of the thorax or chest cavity when the muscles of inspiration contract. Contraction of the diaphragm results in it descending and enlarging the vertical size of the thoracic cavity. The external intercostal muscles contract and raise the ribs slightly to increase the circumference of the thorax. The contraction of these muscles is the “work” required to inspire. The intrapleural pressure becomes more negative during inspiration in relation to atmospheric pressure. This negative intrapleural pressure goes from $-5 \text{ cmH}_2\text{O}$ at the end of expiration to $-10 \text{ cmH}_2\text{O}$ at the end of inspiration. The negative intrapleural pressure is transmitted to the alveolar space. The transpulmonary pressure or the gradient across the lung widens. As a result, the alveoli have a negative pressure during spontaneous inspiration. Pressure at the mouth is still atmospheric. Air flows from the mouth into the alveoli, and the alveoli expand. The volume of gas builds up in the alveoli, and the pressure returns to zero. The air-flow stops. This is the end of inspiration, and no more gas moves into the lungs.

Normal exhalation is passive and does not require any work. The muscles relax, the diaphragm moves upward to its resting position, and the ribs return to their normal position. The volume of thoracic cavity decreases and air is forced out of the alveoli. The thoracic volume decreases to resting, and the intrapleural pressure returns to $-5 \text{ cmH}_2\text{O}$. The pressure inside the alveolus increases during exhalation and becomes slightly positive (i.e., $+5 \text{ cmH}_2\text{O}$). Pressure is lower at the mouth than inside the alveoli. The transairway pressure gradient causes air to move out of the lungs. Exhalation ends when the pressure in the alveoli and the mouth is equal.

This chapter covers the basics of ventilator management. Many Emergency Departments have ventilators ready to use (**Figures 36-1 and 36-2**). They are applied to the patients who require endotracheal

intubation before they are admitted. Refer to a text for more detailed information regarding managing a ventilator.

ANATOMY AND PATHOPHYSIOLOGY

COMPLIANCE

Monitoring changes in compliance is a valuable means of assessing changes in the patient's condition during mechanical ventilation.¹ Compliance usually is measured under conditions of no gas flow. It is referred to as a static compliance or static effective compliance.

RESISTANCE

Resistance, or frictional forces, associated with ventilation is the result of the anatomic structure of the conductive airways and the tissue viscous resistance of the lungs and adjacent tissues.¹ The movement and displacement of structures create resistance to breathing. Tissue resistance remains constant under most circumstances. A patient with lung fibrosis or obesity has increased tissue resistance, but it usually does not change with mechanical ventilation. Tissue resistance increases if a patient develops ascites.

Resistance of the airways is often evaluated during mechanical ventilation. The ability of air to flow through conductive airways depends on the gas density, the length and diameter of the endotracheal tube, the flow rate of the gas through the endotracheal tube, and the gas viscosity. Density, endotracheal tube length, and viscosity remain constant. The diameter of the airway lumen and the flow of gas into the lungs can decrease (e.g., from bronchospasm, increased secretions, mucosal edema, or kinks in the endotracheal tube). The rate at which gas flows into the lungs can be controlled with mechanical ventilation.

More of the pressure for breathing with higher resistance goes to the airways and not the alveoli. This results in a smaller volume of gas available for gas exchange. Another disadvantage of high resistance is that more force must be exerted to get the gas to flow through the obstructed airways. Spontaneously breathing patients use the accessory muscles to generate this increased force. This generates more negative intrapleural pressure and a greater pressure gradient between the upper airway and the pleural space to achieve gas flow. The same occurs during mechanical ventilation. More pressure is exerted by the ventilator to try to move the gas into

the patient's lungs through obstructed airways or through a small endotracheal tube.

TYPES OF VENTILATORS

There are two classes of ventilators.¹ There are those that produce breathing patterns that mimic normally respiration. These are called conventional, and their maximum rate is 150 breaths/min. Others produce respiratory patterns at frequencies much higher than we produce for breathing and are called high-frequency ventilators. These ventilators can produce rates up to 900 breaths/min.

CONVENTIONAL VENTILATORS

Conventional ventilators use respiratory patterns that approximate those produced by normal spontaneous breathing. Tidal volumes clear the anatomic dead space during inspiration, and respiratory rates are in the range of normal rates. Gas transport is by convective flow, and mixing in the alveoli occurs by molecular diffusion.

NEGATIVE-PRESSURE VENTILATION

Negative-pressure ventilation mimics the actual function of the respiratory muscles to allow breathing through normal physiologic mechanisms.¹ The best example is the iron lungs. Negative pressure generated around the thoracic area is transmitted across the chest wall, into the intrapleural space, and into the intraalveolar space. As the intrapleural pressure becomes negative, the space inside the alveoli becomes increasingly negative in relation to the pressure at the mouth. This pressure gradient results in movement of air into the lungs. Expiration occurs when the negative pressure around the chest wall is eliminated. The normal elastic recoil of the lungs and chest wall allows air to flow out of the lungs passively.

Negative-pressure ventilators have several advantages. The upper airway can be maintained without the use of an endotracheal tube. The patient can talk and eat. Negative-pressure ventilation has fewer physiologic disadvantages than positive-pressure ventilation. The normal cardiovascular response is not always present in hypovolemic patients to compensate for the negative pressure on the abdomen. This results in the patient having significant pooling of blood in the abdomen and reduced venous return to the heart. Difficulty accessing the patient complicates care activities.

POSITIVE-PRESSURE VENTILATION

Positive-pressure ventilation occurs when a mechanical ventilator moves air into the lungs using an endotracheal tube or mask.¹ The inflating pressure at the upper airway during inspiration equals the sum of the pressures required to overcome the compliance of the lung and chest wall and the resistance of the airways. The pressure in the alveoli during inspiration progressively builds and becomes more positive. Positive alveolar pressure is transmitted across the visceral pleura. This results in the intrapleural space becoming positive at the end of inspiration, and the ventilator stops delivering positive pressure. Mouth pressure returns to ambient pressure while the alveolar pressure is still positive. This gradient between the alveolus and the mouth causes air to flow out.

DEFINITION OF PRESSURES IN POSITIVE-PRESSURE VENTILATION

BASELINE PRESSURE

Pressures are read from a baseline value.¹ The baseline pressure is normally zero or atmospheric. This indicates that no additional pressure is applied at the airway opening during expiration and before inspiration. The baseline pressure is higher than zero when the ventilator pressure is higher during exhalation. This is called positive end-expiratory pressure (PEEP). PEEP prevents the patient from exhaling to zero or atmospheric pressure. PEEP increases the volume of gas in the lungs at the end of exhalation or increases the functional residual capacity. PEEP applied by the ventilator is called extrinsic PEEP. It prevents de-recruitment or collapse of alveoli. The PEEP to prevent de-recruitment is less than the PEEP initially needed to recruit alveoli and keep them open.

Auto-PEEP or intrinsic PEEP is a complication of positive-pressure ventilation. Air is accidentally trapped in the lungs. This occurs when a patient does not have enough time to exhale before the ventilator delivers another breath.

PEAK PRESSURE

The pressure rises progressively to a peak pressure during positive-pressure ventilation.¹ This is the highest pressure recorded at the end of inspiration. Peak pressure is also called peak inspiratory pressure (PIP) or peak airway pressure. The pressures measured during inspiration are the sum of the pressure required to force gas through the resistance of the airways and the pressure of the gas volume as it fills the alveoli.

PLATEAU PRESSURE

The plateau pressure is measured after a breath has been delivered to the patient and before exhalation.¹ Exhalation is prevented by the ventilator for 0.5 to 1.5 seconds. On the ventilator, select inflation hold or inspiratory pause to get the plateau pressure. Plateau pressure measurement is similar to breath-holding at the end of inspiration when the pressure inside the alveoli and mouth is equal with no flow. The relaxation of the respiratory muscles and the elastic recoil of the lung tissues exert a force on the inflated lungs, creating a positive pressure. The reading is stable during a breath-hold and “plateaus.” The plateau pressure reflects the effect of the elastic recoil on the gas volume inside the alveoli and any pressure exerted by the volume in the ventilator circuit that is acted upon by the recoil of the circuit.

END EXHALATION PRESSURE

Air can be trapped in the lungs during mechanical ventilation if not enough time is allowed for exhalation. The most effective way to

prevent this is to monitor the pressure in the ventilator at the end of exhalation. Air trapping or auto-PEEP is present if no extrinsic PEEP is added and the baseline pressure is greater than the normal baseline.

HOW VENTILATORS WORK

INTERNAL FUNCTION

A ventilator is plugged into an electrical outlet, plugged into a high-pressure gas source, or uses a rechargeable battery. The ventilator operator sets the controls on a control panel (i.e., user interface) to establish the pressure and pattern of gas flow from the ventilator. A control system inside interprets the settings. The control system produces and regulates the desired output.

VENTILATOR COMPONENTS

There are only a few components of a ventilator.¹ A power source or input power (i.e., electrical or gas source) is from electrically powered ventilators, pneumatically powered ventilators, or combined power ventilators. There is a positive- or negative-pressure generator. The control systems and circuits consist of open and closed loop systems to control ventilator function, the control panel or user interface, and the pneumatic circuit. The power transmission and conversion system results in volume displacement using flow control valves. The output from the ventilator controls flow waveforms, pressure, and volume.

POWER SOURCE OR INPUT POWER

The ventilator's power source enables the machine to ventilate the patient. The power source may be electrical power, pneumatic or gas power, or a combination of the two. Electrically powered ventilators rely on electricity. The electrical source may be a battery or a wall outlet. Battery power usually is used for a short time (e.g., transporting a patient). The battery can also be used as a backup power source. Some ventilators use a compressed gas for power. These machines use 50 psi gas sources and have built-in internal reducing valves to allow the operating pressure to be lower than the source pressure.

POSITIVE- AND NEGATIVE-PRESSURE GENERATORS

Ventilator gas flow into the lungs is based on different methods of changing the transrespiratory pressure or the pressure at the airway opening minus pressure at the body surface. A ventilator can control pressure at the mouth or around the body. A negative-pressure ventilator generates negative pressure at the body surface that is transmitted to the pleural space and the alveoli. A pressure gradient develops between the airway opening and the alveoli. This results in air flow into the lungs. The volume delivered depends on the pressure difference between the alveolus and the pleural space as well as the lung and chest wall compliance.

Gas flows into the lung with positive-pressure ventilation because the ventilator establishes a pressure gradient generating a positive pressure at the airway opening.

CONTROL SYSTEMS AND CIRCUITS

The control system or control circuit or decision-making system regulates ventilator function. The computer or microprocessor control is the loop system. Most ventilators that are not microprocessor controlled are called open loop or “unintelligent” systems.

The control is set (e.g., tidal volume), and the ventilator delivers that volume to the patient circuit. This is called an unintelligent system because the ventilator cannot be programmed to respond to changing conditions. An open loop ventilator cannot adjust its function to correct for the leakage. It outputs a set volume and does not measure or change it. Closed loop systems are often described as “intelligent” systems because they compare the set control to the measured control. Differences between the two alter the volume delivery. An example of a closed loop system is mandatory minute ventilation (MMV). A minimum minute ventilation that is lower than the patient’s spontaneous minute ventilation is selected. The ventilator monitors the patient’s spontaneous minute ventilation. If the patient spontaneous minute ventilation falls below a set value, the ventilator increases its output to meet the minimum set minute ventilation.

CONTROL PANEL OR USER INTERFACE

The control panel or user interface is located on the surface of the ventilator. It is set and monitored. The internal control system uses the settings to control the function of the drive mechanism. The control panel has ways for setting alarms, FIO_2 , inspiratory time, respiratory rate, and tidal volume. These controls regulate the variables of flow, pressure, time, and volume. The value for each of these can vary within a wide range. Alarms can be set to respond to changes in a variety of monitored variables.

PNEUMATIC CIRCUIT

A pneumatic circuit or pathway is a series of tubes that allow gas to flow inside the ventilator and to the patient. The pressure gradient created by the ventilator generates the flow of gas. The gas flow passes through the pneumatic circuit to the patient. The gas is directed from the generating source inside the ventilator, through the internal pneumatic circuit to the ventilator’s outside surface, and through an external circuit to the patient. The gasses are exhaled through an expiratory limb and exhalation valve.

The basic elements of a circuit are simple. The main inspiratory line connects the ventilator output to the patient’s airway adapter or connector. The airway adapter is also called a patient adapter or Y connector because of its shape. The expiratory line carries expired gas from the patient to the exhalation valve, which releases exhaled gas into the room.

ADJUNCTS TO THE CIRCUIT

The above essential parts are aided by other components added to the circuit to optimize gas delivery and ventilator function.¹ A device to warm and humidify inspired air is often used. This requires a thermometer to measure the temperature of inspired air. An apnea or low-pressure alarm indicates leaks or if the patient is not ventilating adequately. A nebulizer to power a micronebulizer delivers aerosolized medications. A volume-measuring device determines the patient’s exhaled volume. Bacterial filters clear the gas administered to the patient and exhaled by the patient. A pressure gauge measures pressures in the upper airway.

Normal spontaneous breathing provides 100% relative humidity at 37°C and contains 44 mg/L of water (i.e., absolute humidity). Conditioning of inhaled gasses typically occurs down to the fourth or fifth generation of subsegmental bronchi and is called the isothermic saturation boundary. The conditioning of inspired air is normally provided by the nose and upper airway. These structures are bypassed by the endotracheal tube during mechanical ventilation. A humidifier must be added to the ventilator circuit to make

up for this loss. The humidification system for the ventilator should provide at least 30 mgH₂O/L of absolute humidity at a range of 31°C to 35°C for all available flows. Some prefer a delivered temperature range of 35°C to 37°C.

Humidity is commonly provided by heated humidification systems. Devices in this category include active heat and moisture exchanger (AHME), passover, vapor phase, and wick humidifiers. Heated humidifiers typically include a servo-controlled heater, a temperature readout, and a temperature alarm. The temperature probe is placed close to the patient airway. The high-temperature alarm is set at 37°C to 38°C so that inspired gas does not exceed 37°C. A minimum alarm setting of 30°C is appropriate. Condensate will accumulate in the circuit when the temperature in the patient circuit is less than the temperature of the gas leaving the humidifier. A cool room environment contributes to the condensate accumulation. Using heated wire circuits on the inspiratory and expiratory lines can significantly reduce this condensation.

The relative humidity in the circuit decreases if the temperature of the gas in the patient circuit is higher than the humidifier. This can happen in heated wire circuits. Drying of secretions can occur if a deficit exists between the amount of humidity provided and the amount needed by the patient. Thick secretions that are hard to suction and the presence of bronchial casts and mucous plugs are signs of drying of the airways.

ALARMS

Alarms warn of possible dangers related to the ventilator system. Low-pressure alarms are usually set at 5 to 10 cmH₂O below peak inspiratory pressure. They detect disconnections and leaks in the system. High-pressure alarms are set at 10 cmH₂O above peak inspiratory pressure and usually end inspiration when activated. They indicate when the patient coughs, if secretions increase, if compliance drops, or if there are kinks in the endotracheal tube or circuit tubing. Low PEEP/continuous positive airway pressure (CPAP) alarms are usually set at 2 to 5 cmH₂O below the PEEP level and indicate when the PEEP or CPAP level has dropped. Apnea alarms are used to monitor mandatory and/or spontaneous breaths. An apnea period of 20 seconds is the maximum accepted. Apnea alarms can be set so the patient will not miss two consecutive breaths. Apnea settings provide full ventilator support for the patient if apnea occurs.

Most ventilators have a ratio alarm or indicator that warns when the inspiratory time is more than half the set cycle time. Some ventilators will automatically shut off at the end inspiration if the expiration time gets so short that the patient does not have time to exhale. Low gas source alarms alert that the available high-pressure gas source is no longer functional. These alarms can be critical for newer microprocessor ventilators that rely on high-pressure gas to function. The alarm cannot be silenced if gas is critical to ventilator operation.

Other ventilator alarms include low tidal volume, low and high expiratory volume, low and high breath rates, and low and high oxygen percentage. There are no predetermined levels for setting these parameters. Use the appropriate judgment when setting alarms to indicate possible changes in patient condition.

FLOW CONTROL VALVES

Modern ventilators use flow control valves to control or direct gas flow by opening and closing completely or in small increments. These valves are motor-based mechanisms. They have a rapid response time and great flexibility in flow control. Flow control valves include proportional solenoid valves, stepper motors with valves, and digital valves with on/off configurations.

GRAPHIC DISPLAYS

Modern ventilators provide graphic displays in loops and waveforms. Loop displays show one variable plotted against another. Waveform displays show flow, pressure, and volume on the vertical axis with time on the horizontal axis.

INDICATIONS FOR MECHANICAL VENTILATION

Respiratory support must start with noninvasive support using the noninvasive ventilation, unless there are clear contraindications for the use of noninvasive methods (e.g., patients with pending respiratory failure). The concept of escalating respiratory support is essential because the invasive respiratory support of extracorporeal membrane oxygenation (ECMO) and mechanical ventilation are associated with major hazards. The indications for intubation and mechanical ventilation initiation are discussed in Chapters 16 and 18.

The main indications for mechanical ventilation include apnea, respiratory distress, hypoxemia, and hypercapnia. It is intuitive to restore ventilation in apneic patients or patients who lost their airway. Patients exhibiting respiratory distress, increased work of breathing, or increased respiratory rate (e.g., the earliest sign of respiratory distress, accessory muscle use, tachycardia, and diaphoresis) face respiratory fatigue and failure. Mechanical ventilation helps to unload the increased work of breathing and stop the vicious circle of acidosis associated respiratory depression. Hypoxemia is defined as the partial pressure of oxygen in arterial blood (PaO_2) < 60 mmHg with PaO_2 values adjusted to patient age. Mechanical ventilation is usually initiated at a fraction of inspired oxygen (FIO_2) of 1.0 or 100%. This high FIO_2 is diagnostic and therapeutic. Patient failure to respond to high FIO_2 points to shunt pathology as the contributor to hypoxemia. **FIO_2 must be weaned as soon as the patient becomes stable.**

Severe hypercapnia is a high carbon dioxide (CO_2) and acidosis that suppresses respiratory muscle contractility. Hypercapnia is defined as a partial pressure of CO_2 (PCO_2) > 50 mmHg. This definition may not be applicable in certain situations as the baseline in partial pressure of CO_2 in arterial blood (PaCO_2) in patients with chronic CO_2 retention may exceed 50 mmHg. Permissive hypercapnia may be deliberately instituted to allow for more liberal management in PaCO_2 targets. Hypercapnic failure in chronic obstructive pulmonary disease (COPD) must take into consideration the patient's clinical status, the trend in CO_2 level, and the pH decline. PaCO_2 levels > 50 mmHg indicates a significant rise in patients with acute hypercapnic failure secondary to muscle disorders (e.g., Guillain-Barré syndrome, myasthenia gravis, and spinal cord injury).^{2,3}

CONTRAINDICATIONS TO MECHANICAL VENTILATION

All contraindications are relative. These include a tension pneumothorax and hypovolemic shock. Mechanical ventilation with high tidal volumes and PEEP will hinder the respiratory rate and worsen the hemodynamics. Endotracheal intubation followed by spontaneous breathing is a more appropriate option in hypovolemic patients. Mechanical ventilation will prevent healing of bronchopleural fistulas. Lung isolation of bronchopleural fistulas is recommended when mechanical ventilation is indicated. High PEEP contributes to high intracranial pressure (ICP).^{4,5} Right ventricular failure may become worse using mechanical ventilation.^{6,7} These relative contraindications may be the reason(s) the patient needs to be intubated and mechanically ventilated (e.g., to manage high ICP, to offload the work of breathing, or to offload the failing heart).

TABLE 36-1 Summary of Techniques

Mode of ventilation	Set variables	Mandatory breath	Spontaneous breath
ACV	Flow Flow shape (constants or decelerating) Respiratory rate Tidal volume	Fixed volume Respiratory rate	The spontaneous breath is similar to preset tidal volume
SIMV	Flow Pressure support Respiratory rate Tidal volume	Fixed volume Respiratory rate	Any respiratory rate with tidal volume varies according to pressure support
PCV	Pressure Respiratory rate Tidal volume	Set pressure Variable tidal volume	Depends on the mode PCV-ACV: same as tidal volume as the mandatory PCV-SIMV: tidal volume varies with the preset pressure support
PSV	Pressure	None	Patient efforts determine the respiratory rate and tidal volume assisted by the preset pressure

TECHNIQUES OF MECHANICAL VENTILATION

Understanding the different techniques of mechanical ventilation requires knowledge of control variables and phase variables (Tables 36-1 and 36-2).^{8,9}

CONTROL VARIABLES

There are three control variables. These are volume, pressure, and flow. Only one control variable is set and is called the independent variable. The other two variables will be the dependent variables. If the volume is constant (i.e., volume controlled), the pressure varies inversely with lung compliance. If the pressure is set or constant (i.e., pressure controlled), the volume varies in the same direction as lung compliance.

PHASE VARIABLE TRIGGERS

Triggers are what initiates the breath. The inspiratory cycle starts when the triggers are met. There are four main basic triggers. The time trigger is the fixed number of breaths per time unit and is mandatory. Synchronized intermediate ventilation (SIMV) and assist controlled ventilation (ACV or AC) are time-triggered modes. Flow trigger breathing starts when the patient breathes to a predetermined amount of flow. Pressure support ventilation (PSV) is an example of flow-triggered breathing. Pressure trigger breathing starts when

TABLE 36-2 Summary of Ventilator Modes

	Cycled	Initiated	Limitation
Continuous positive airway pressure (CPAP)	Flow	Flow or pressure	Pressure
Pressure control (PC)	Time	Time	Pressure
Pressure-regulated volume control (PRVC)	Volume	Time	Volume
Pressure support (PS)	Flow	Flow or pressure	Pressure
Synchronized intermittent ventilation (SIMV)	Time or volume	Flow, pressure, or time	Volume
Volume control (VC)	Time or volume	Time	Volume
Volume support (VS)	Flow	Flow or pressure	Volume

the patient creates negative pressure in the circuit. Volume trigger breathing starts when the patient breathes in a small volume.

PHASE VARIABLE CYCLES

The cycle is what switches from inhalation to exhalation and vice versa. Volume cycled is determined when the predetermined volume is achieved. The breathing effort stops and exhalation starts. Flow cycled results in stopping of the breathing once flow drops to a predetermined value. Pressure cycled stops the inhalation once the predetermined peak pressure is achieved and exhalation begins. Time cycled is timed inspiration regardless of the flow, pressure, or volume.

PHASE VARIABLE LIMITS

The limit is what stops the breathing. The set value of the limit cannot be exceeded during inspiration. There are limits to flow, minute ventilation, pressure, and volume. An example is during volume-controlled ventilation. If peak airway pressure reaches the pressure limit, the ventilator will stop inspiration and start the expiration phase.

THE DIFFERENT TECHNIQUES OF MECHANICAL VENTILATION

There are four conventional commonly used modes for mechanical ventilation (**Tables 36-1 and 36-2**).¹⁰ These are assisted control ventilation (AC or ACV), synchronized intermittent mandatory ventilation (SIMV) derived from intermittent mandatory ventilation (IMV), pressure control ventilation (PCV), and pressure support ventilation (PSV). Other modes or techniques are not as commonly used but are growing. These include airway pressure release ventilation (APRV), pressure-regulated volume control (PRVC), volume support ventilation (VSV), and proportional assist ventilation (PAV). All are made possible by advances in ventilator software. High-frequency oscillatory ventilation is widely used but not classified as a conventional mode of mechanical ventilation.

ASSISTED CONTROLLED VENTILATION

The machine maintains a constant number of breaths and a constant tidal volume. The patient can trigger the ventilation, and this is variable. The tidal volume remains the same as the ventilator-delivered volume. There is constant flow and constant volume. The variables of airway and plateau pressure vary according to lung compliance. The advantages of ACV mode include the decreased work of breathing. ACV will rest patients with increased work of breathing. ACV provides adequate minute ventilation.

There are many disadvantages to ACV. There is a higher risk of barotrauma. ACV causes patient discomfort because of constant flow throughout the inspiratory cycle compared with PCV, which has a descending flow pattern. **The ventilated patient needs mismatch.** Set the tidal volume below the patient's requirement. Tidal volume hunger results in the patient triggering the ventilator more often and increases the work of breathing. Respiratory alkalosis secondary to mandatory big tidal volumes occurs if the set tidal volume is higher than patient requirements. There is a risk of auto-PEEP secondary to mandatory high tidal volumes, especially in patients with obstructive disorders. Prolonged use of ACV may lead to respiratory muscle weakness and atrophy.

SYNCHRONIZED INTERMITTENT VENTILATION

The ventilator delivers the preset respiratory rate and tidal volume. The patient can trigger the ventilation, and it is variable. The tidal volume varies according to patient effort and the pressure support in each added breath. The triggers are time and flow when the patient

initiates the breath. The cycle is timed with volume control. There are limits on flow, pressure, and volume.

There are numerous advantages to SIMV. It is more comfortable in awake patients or those with minimal sedation. The patient determines the respiratory rate and tidal volume. **SIMV allows a guaranteed minute ventilation if the patient fails to trigger a breath.** The patient-determined tidal volume helps the ventilator-needed mismatch and lowers the risk of respiratory alkalosis compared to ACV. Patients use their respiratory muscles, which lowers the risk of muscle atrophy.

Increased work of breathing occurs if excessive effort is needed during the spontaneous breath and inadequate pressure support is available. There is a risk of hypoventilation if the patient fatigues and the spontaneous breath does not meet the patient's needs combined with the low set mandatory tidal volume.

PRESSURE-CONTROLLED VENTILATION

PCV is the mode that controls pressure with little control of tidal volume and minute ventilation. The higher the set pressure, the bigger is the tidal volume achieved in patients with normal lung compliance. **PCV is mainly used in low-compliance conditions to decrease the risk of barotrauma.** PCV, continuous mandatory ventilation (CMV), IMV, SIMV, and ACV can be pressure controlled. The trigger to PCV is flow or time. The cycle is time controlled. There are limits on flow and pressure. PCV results in better oxygenation with a higher PaO₂ in the patient because of the maintained lung distention during inspiration.³

PCV results in a variable tidal volume and fluctuating minute ventilation. Decreased lung compliance results in decreases in the tidal volume with PCV. Increased airway resistance decreases the tidal volume. Increase in tidal volume is seen in fixed inspiration-to-expiration (I:E) ratios.

PRESSURE SUPPORT VENTILATION

PSV is a form of augmented spontaneous breathing. The patient decides their respiratory rate and tidal volume. The tidal volume varies according to the set pressure support. Exhalation is a passive process. **PSV can only be used in patients who can initiate breathing.** Flow triggers the ventilator breathing and cycle. The decrease in flow to 25% of the predetermined value ends inspiration and starts passive exhalation. Time cycling can be used as backup mode. There are limits on flow and volume. **PSV is considered the most comfortable form of mechanical ventilation,** with patients report the most comfort with this method. The patient decides the expiratory flow, inspiratory flow, and respiratory rate.

PSV decreases the work of breathing with adequate pressure support. This manifests as improved tidal volume and a drop in the respiratory rate. PSV is used in preparation for weaning from mechanical ventilation. Patients with adequate tidal volume on minimal pressure support (i.e., <7 mmHg) to overcome the endotracheal tube resistance are potential candidates for mechanical ventilation discontinuation.

PSV risks hypoventilation if the tidal volume drops with poor lung mechanics. PSV is poorly tolerated if the patient has an obstructive lung disorder. It is associated with low tidal volumes and hypoventilation. PSV may lead to patient-ventilator asynchrony. This asynchrony happens when the COPD patient needs a longer time to fill their lungs. The pressure continues to rise in this prolonged inspiratory phase when the patient decides to start expiration.

INITIAL VENTILATOR SETTINGS

Place the patient in a semi recumbent position if no contraindications exist.¹¹ Provide analgesia, paralysis, and sedation.¹²⁻¹⁹ Select the

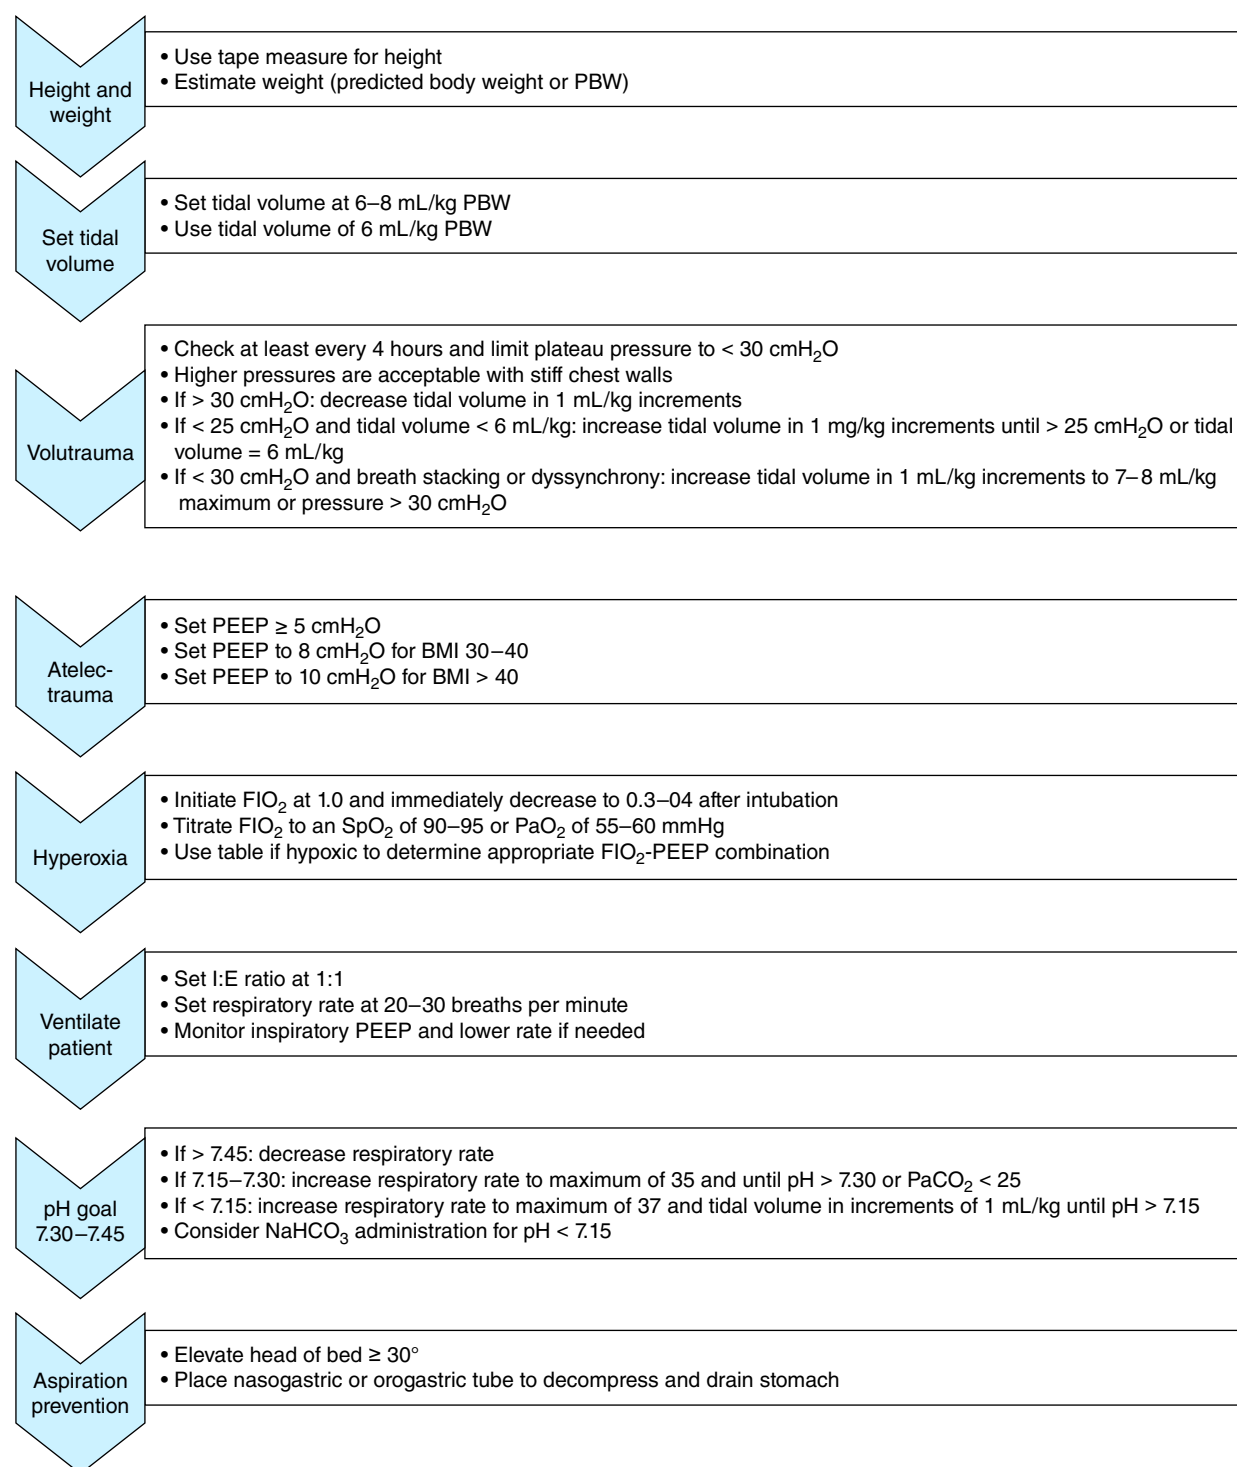

FIGURE 36-3. Example of a protocol for ventilator settings. (Modified from references 20, 21, 23, and 48.)

ventilation mode, FIO₂, flow rate, I:E ratio, PEEP, respiratory rate, and tidal volume (**Figure 36-3** and **Tables 36-3 to 36-5**).^{9,20-22} It is a universal recommendation to start at a low tidal volume of 6 to 8 mL/kg.²³ Set the tidal volume lower in acute respiratory distress syndrome to prevent volume-induced lung injury. Healthy adults can be started at 10 to 12 breaths/min. Patients with restrictive lung disorders can be started at rates of 18 to 20 breaths/min to compensate for the low tidal volume ventilation.

Set the flow between 40 and 100 L/min. Lower flow rates will lengthen the inspiratory time and improve alveoli recruitment. Higher flow rates will lengthen the expiratory time and improve

lung emptying. The healthy patient spends double the time in expiration than in inspiration. The I:E ratio is usually set at 1:2. Use inverse ratios of 1:1 and 2:1 for alveoli recruitment. The FIO₂ begins at 1.0 or 100% for diagnostic and therapeutic purposes. Titrate the oxygen to prevent hyperoxia and decrease any mortality associated with hyperoxia.^{24,25}

PEEP is applied to open the collapsed alveoli, keep alveoli open, increase the functional residual capacity (FRC), and improve oxygenation. PEEP decreases atelectasis and decreases the shear forces by keeping the alveoli open. **PEEP must be titrated to patient physiology.** Add PEEP gradually and assess the effect on compliance and

TABLE 36-3 Initial Ventilator Settings for Common Conditions

Condition	Ventilator mode	FIO ₂	I:E ratio	PEEP (cmH ₂ O)	Respiratory rate/minute	Tidal volume (mL/kg)	Comments
Normal	SIMV-VC	1.0*	1:2	4–5	10–14	8	Do not cause harm. Use lung protection settings. Adjust settings to keep O ₂ and CO ₂ normal.
Acute respiratory distress syndrome	SIMV-VC	1.0*	2:1	10–15	10–14	6	Watch pressures. Accept higher CO ₂ . Titrate FIO ₂ and PEEP to provide oxygenation. Lower tidal volume as necessary. Recruit alveoli. Avoid atelectasis. Reduce shunting.
Asthma or COPD	SIMV-VC	1.0*	1:4 or 1:5	0–5	8–10	6	Maintain pH > 7.15. Watch for auto-PEEP, barotrauma, breath stacking, and volutrauma. Allow adequate exhalation. May have to accept higher peak pressures. Consider permissive hypercapnia.
Head injury	SIMV-VC	1.0*	1:2	5	14–16	6–8	Avoid high intrathoracic pressure, which reduces venous return. Avoid high PEEP. PCO ₂ levels of 35–40.
Hypovolemia	SIMV-VC	1.0*	1:2	0–4	10–12	6	Avoid high intrathoracic pressure, which reduces venous return. Avoid high PEEP.
Metabolic acidosis	SIMV-VC	1.0*	1:1 or 1:2	5	20–30	8–10	Compensate for acidosis with rate. Titrate rate and tidal volume by arterial blood gases.
Obesity	SIMV-VC	1.0*	1:1 or 2:1	10–15	12–14	8–10	Minimize disconnections and suctioning to prevent atelectasis. Avoid atelectasis and shunting.

*Start at 1.0 and titrate down to 0.4 or a pulse oximetry of 95% or PO₂ > 70; avoid hyperoxia.

Increase respiratory rate	Decrease	Increase
Increase tidal volume	Decrease	Increase

oxygenation. Excessive PEEP will lead to lung overdistention with detrimental effects on the lung and hemodynamics.

Adjust the ventilator settings to maintain the PaCO₂ and PaO₂ (Table 36-6). The allowable PaCO₂ and PaO₂ will vary and depend on the patient's condition. Attempt the following after intubation to decrease mortality: arterial blood gas, capnography, chest radiography, early sedation, gastric emptying, and tidal volumes appropriate for the condition.²⁶

COMPLICATIONS OF MECHANICAL VENTILATION

There are many complications associated with mechanical ventilation.^{27,28} High tidal volumes can lead to shear stress on the alveoli. Limit the tidal volume to 6 to 8 mL/kg.^{29,30} The ventilator can induce diaphragm dysfunction. Select mechanical ventilation modes that encourage patient effort. Attempt early liberation from mechanical ventilation. Ventilator-associated pneumonia is common.³¹ Prevent aspiration using head elevation, oral hygiene, and placement of tubes subglottically.³² Barotrauma can injure the alveoli.³³ Limit the plateau pressure to <35 mmHg and the transpulmonary pressure. Low tidal volumes lead to atelectasis (i.e., atelectrauma). Apply adequate PEEP. Hyperoxia can cause increased mortality.²⁴ Use the lowest FIO₂ possible to maintain the saturation > 90.

Ventilator alarms may ring, and the patient may worsen. The alarms may be set too low, or the patient may have a problem (Table 36-7). First determine if it is a true alarm due to high or low airway pressure. Look for the cause, and correct this if found. The patient on a ventilator may worsen. Use the mnemonics **DOPES** and **DOTTS** to assess for the common reasons for worsening (Table 36-8). Look for the cause of patient's worsening status and correct this if found.

The endotracheal tube cuff can be a source of problems. Under-inflated cuffs can result in air leaks and aspiration pneumonia. Overinflated cuffs can result in fistulas from the trachea, tracheal mucosal necrosis, and tracheal perforation. The IntelliCuff (Hamilton Medical AG, Switzerland) was developed to provide and maintain appropriate cuff pressure (Figure 36-4). This is integral to their ventilators and avoids manual monitoring and adjustment to the

TABLE 36-7 Troubleshooting Ventilator Alarms

High airway pressure	Low airway pressure
Air trapping	Air escaping chest (drains, tubes, or wounds)
Bronchospasm	Endotracheal tube cuff deflated
Endotracheal tube blocked (biting, cough, gagging, mucous)	Esophageal intubation
Endotracheal tube in main bronchus	Tidal volume set too low
Maximum pressure set too low	Ventilator circuit disconnected
Patient-ventilator dyssynchrony	
PEEP set too high	
Pneumothorax	

TABLE 36-8 Mnemonics for the Crashing Ventilator Patient

DOPES mnemonic	DOTTS mnemonic
Displaced endotracheal tube or cuff not inflated	Disconnect ventilator and bag patient
Obstruction of endotracheal tube	Oxygenate with bag-valve-mask and feel for resistance
Pneumothorax	Tube function and position (check for kinking, migration, or plugging)
Equipment malfunctioning	Tweak the ventilator settings
Stacking breaths or auto-PEEP	Sonography (look for mainstem intubation or pneumothorax)

cuff. It continuously monitors endotracheal cuff pressure, automatically adjusts the cuff, and decreases complications.³⁴⁻³⁸ The IntelliCuff attaches to the inflation port of a standard endotracheal tube and sounds an alarm if the cuff leaks or the endotracheal tube is disconnected.

The ventilated patient may become anxious or show signs of respiratory distress (Table 36-9).³⁹ The biggest problems are hypoxia and pain, with hypoxemia being life threatening. Look for the signs of these events and make any corrections needed.

AFTERCARE OF MECHANICAL VENTILATION

Provide sedation to allow synchrony with the ventilator. Sedation must be interrupted for patient neurologic assessment and

TABLE 36-9 Causes of Patient Anxiety and Respiratory Distress

Adverse drug effects	Evaluate medications Explain interventions Limit staffing changes Orient to surroundings Provide calming and reassurance
Air leak volume loss	Correct air leaks in endotracheal (ET) cuff, ET tube, or ventilator Ensure correct tidal volume is delivered
Airway irritation	Bronchospasm, cough, or secretions Drainage of tube condensation into the patient's airway Suction only as needed Thin respiratory secretions
Attempting to speak	Implement communication system (e.g., patient writing)
Biting ET tube	Decreased tidal volume and peak airway pressure alarms Insert bite block Paralyze and sedate patient Try to reason with patient
ET tube displacement or moving	Secure ET tube to patient with holder Support ET tube on ventilator arm Use caution with movement or turning
ET tube or holder causing discomfort or pressure erosion	Monitor skin breakdown Reposition ET tube and holder Secure ET tube with holder
Inadequate inspiratory flow rate	Adjust flow rate setting on ventilator to eliminate air hunger Manually ventilate patient synchronous with their breaths
Low tidal volume alarm	Decreased lung compliance Increased airway resistance Pressure limit alarm
Peak airway pressure alarm	Decreased lung compliance Increased airway resistance Pressure limit alarm
Sleep deprivation	Coordinate interruptions Evaluate medications Explain interventions Limit staffing changes Orient to surroundings Provide calming and reassurance Provide noise cancellation earplugs or headsets Relaxation technique implementation

to assess ventilator liberation. Assess the patient for mechanical ventilation-associated complications. **The goal is to work toward liberation of mechanical ventilation as early as possible.** Some patients may not be ready for ventilator liberation and extubation (Table 36-10).⁴⁰

LIBERATION FROM MECHANICAL VENTILATION

Patients are considered for weaning from mechanical ventilation when they pass the three-step approach.^{23,41,42} One to two times a day, check if the patient can be liberated from the ventilator. Step 1 is the resolution of the cause of intubation and mechanical ventilation. An example is the patient with upper airway edema. They must have an adequate cuff-leak test before the weaning trial. Patients with an altered mental status or coma must regain their baseline level of consciousness. Patients intubated after hemodynamic instability must exhibit adequate perfusion and somewhat normal vital signs.

Step 2 is stable physiologic conditions. The patient must be hemodynamically stable (i.e., systolic blood pressure ≥ 90 mmHg) with minimal vasopressor and inotropic support. There should be minimal ventilation support, an FIO_2 of ≤ 0.4 or 40%, pressure support ≤ 5 mmHg, PEEP ≤ 5 mmHg, adequate oxygenation, and a normal

TABLE 36-10 Predictors of Failed Extubation

Airway obstruction	Airway edema Airway trauma Anasarca COPD Multiple attempts to secure the airway Pneumonia Pulmonary edema Prolonged intubation Reactive airway disease Recent upper respiratory infection Reduced lung compliance Sleep apnea
Failure to oxygenate	Hypoventilation Pneumonia Pulmonary contusion(s) Pulmonary edema Ventilation-perfusion mismatch
Failure to ventilate	Abdominal distension Malnutrition Muscle weakness or wasting Residual effects of paralysis and sedation Residual muscle weakness Splinting from torso pain
Inability to clear respirator secretions	Altered mental status Excessive secretions Neuromuscular weakness

work of breathing. The patient should be afebrile. Laboratory analysis should show normal acid-base balance, phosphorus levels, and potassium levels. The patient should be conscious with minimal sedation, have an adequate cough reflex, and have an adequate gag reflex. There should be total reversal of paralysis in the patient who received paralytics.

Step 3 is normal lung mechanics. The patient must have acceptable spontaneous breathing. The patient's respiratory shallow breathing index (RSBI) should be <105 (i.e., respiratory rate \div tidal volume). A vital capacity of 10 mL/kg of ideal body weight (IBW) is required. The maximum negative inspiratory pressure should be < -30 mmHg. The thoracic compliance should be > 25 mL/1 cmH₂O. The measured work of breathing should be <0.8 J/L.

Following the three-step approach is essential for success of mechanical ventilation liberation. Reintubation is associated with worse outcomes. A spontaneous breathing trial (SBT) can be initiated for the patient who meets the criteria for extubation. SBT can be performed using T-piece, PSV ≤ 5 , or automatic tube compensation. The patient can be extubated in 30 minutes after SBT initiation if the following criteria are met: no abnormal breathing, no diaphragm, no marked accessory muscle use, no signs of increased work of breathing, no tachycardia, $\text{PaO}_2 \geq 60$ mmHg, pH of 7.30, respiratory rate <25 , RSBI <105 , $\text{SpO}_2 > 90$, and spontaneous tidal volume > 4 mL/kg calculated predicted body weight. High-risk airways can be extubated over an exchange catheter. High-risk patients can be extubated to noninvasive ventilation or a high-flow nasal cannula to decrease the risk of reintubation (Chapter 11).⁴³⁻⁴⁷

SUMMARY

Mechanical ventilation is a lifesaving measure. Prolonged mechanical ventilation is associated with complications and morbidities. A thorough understanding of the indications and different modes of mechanical ventilation is essential for successful application. The common terms used with mechanical ventilation should be known

TABLE 36-11 Definitions of Patient and Ventilator Parameters

- I:E ratio: The relative amount of time of inspiration to expiration. It is usually set between 1:2 and 1:3.
- Fraction of inspired oxygen (FIO₂): The inspired oxygen concentration from 0.21 (i.e., 21% or room air) to 1.0 (i.e., 100%).
- Functional residual capacity: The volume of gas in the lungs at the end of expiration.
- Mandatory breath: The timing or volume of the breath is controlled by the ventilator that triggers the breath.
- Minute ventilation: The volume of gas entering or exiting the lungs per minute. It is normally between 5 and 10 L/min.
- Peak airway pressure: The total (highest) pressure measured in cmH₂O required to deliver the tidal volume.
- Peak flow or peak inspiratory flow: The highest flow or speed set to deliver the tidal volume during inspiration. Higher flow rates deliver the gas faster at shorter inspiratory times.
- PEEP: The positive pressure maintained at the end of expiration to keep the alveoli open.
- Plateau pressure: The pressure, measured in cmH₂O, to distend the lung.
- Respiratory rate: The number of breaths per minute. It is usually set between 10 and 20 breaths/min.
- Spontaneous breath: The patient controls the timing and volume of the breath.
- Tidal volume: The volume of gas during inhalation or exhalation. It is usually set between 6 and 12 mL/kg.
- Trigger sensitivity: The effort required by the patient to trigger a ventilator breath.

Source: Modified from reference 39.

by all Emergency Physicians (**Table 36-11**). Efforts should be focused on mechanical ventilation liberation as soon as the patient meets criteria for safe extubation.

Cardiac Ultrasound

Basem F. Khishfe

basic cardiac anatomy, the indications for emergency echocardiography, techniques, and image interpretation.

ANATOMY AND PATHOPHYSIOLOGY

INTRODUCTION

Cardiac ultrasound (US) or basic echocardiography has been proven to be an invaluable tool for identifying critical pathology and directing decision making in the Emergency Department (ED).¹ Cardiac US is a key element in the evaluation of the trauma patient, the cardiac arrest patient, and the patient with undifferentiated hypotension.²⁻⁶ Even though cardiac ultrasonography can be challenging, an Emergency Physician (EP) can become competent in basic cardiac ultrasonography with practice. The EP must have a keen grasp of the spatial anatomy of the heart to properly perform and interpret the US examination. Cardiac US can help EPs to risk-stratify patients and guide resuscitative efforts. Pericardial tamponade is a difficult diagnosis to make without cardiac US. A quick bedside US can assess a patient's cardiac activity, global cardiac function, presence or absence of an effusion, and volume status. This chapter will cover

GENERAL ANATOMY AND PHYSIOLOGY

It is essential to know the anatomy of the heart before performing any US examination (**Figure 37-1**). The heart is a three-dimensional organ that lies obliquely in the middle of the chest. It consists of four chambers: the left atrium, the right atrium, the left ventricle, and the right ventricle. The atria are thin-walled muscular structures. The ventricles are more voluminous and muscular, with the left ventricle having the thickest wall. The base of the heart is the superior portion. It is formed by the left atrium and, to a lesser extent, the right atrium. The apex of the heart consists of the inferolateral portion of the left ventricle. The anterior surface of the heart abuts the chest wall and is mainly formed by the right ventricle. The left ventricle forms the majority of the inferior surface, with the inferior portion of the right ventricle making a minor contribution. The heart has two axes, and both are used extensively in ultrasonography.

FIGURE 37-1. The cardiac anatomy. The long axis of the heart (*long arrow*) extends from the base to the apex. The short axis (*short arrow*) is a transverse slice perpendicular to the long axis.

The long axis extends from the base to the apex, roughly along a line from the right shoulder to the left hip. The short axis slices the heart transversely and perpendicular to the long axis, roughly along a line from the left shoulder to the right hip.

The right heart delivers blood to the lungs to be oxygenated, and the left heart distributes it to the rest of the body. The right atrium receives deoxygenated blood from the body via the superior and inferior vena cava (IVC). Blood flows from the right atrium through the tricuspid valve and into the right ventricle during diastole. Blood is pumped from the right ventricle through the pulmonary valve and into the pulmonary artery during systole. The blood gets oxygenated in the lungs and then flows into the left atrium via the pulmonary veins. Blood flows across the mitral valve into the left ventricle during diastole. It is then pumped by the left ventricle for distribution to the body via the aorta during systole.

The heart is contained within the two-layered pericardial sac. The visceral pericardium is a single layer of cells in direct approximation with the epicardium. The tougher outer fibrous parietal pericardium surrounds the visceral pericardium. The two layers form a potential space that contains a small volume of fluid (approximately 20 to 50 mL).⁷ This pericardial fluid allows the heart to freely move within the fibrous pericardium. Larger volumes of fluid can collect in this potential space in pathologic states.

ULTRASOUND FOR SUSPECTED PERICARDIAL FLUID

A pericardial effusion is a collection of fluid in the space between the pericardium and epicardium. A variety of conditions can lead to this space being filled by fluid, pus, or blood. It can be due to trauma, uremia, infection, neoplasm, connective tissue disorders, iatrogenic complications, idiopathic conditions, chyle, and numerous other rare causes.^{8,9}

The diagnosis of a pericardial effusion should be considered in any patient presenting with shortness of breath, chest pain, and decreased exercise tolerance. Hypotension, distended neck veins, pulsus paradoxus, a pericardial rub on physical examination, and low voltage or electrical alternans on electrocardiogram (ECG) are all consistent with a pericardial effusion. Unfortunately, most of these findings are neither sensitive nor specific for a pericardial effusion or cardiac tamponade.¹⁰ Hence, cardiac US is critical in making the diagnosis. Mandavia and colleagues investigated the ability of EPs to diagnose a pericardial effusion with US.¹ Of the 515 patients enrolled, 103 had pericardial effusion identified by the EPs, for a sensitivity of 96% and a specificity of 98% according to the comparative standard. Cardiac tamponade occurs when the pericardial fluid impedes the ability of the ventricles to fill and leads to decreased cardiac output and cardiovascular collapse.^{8,11} Several sonographic signs suggestive of tamponade physiology have been described, although appreciation of it may be subtle. **The most important finding is a circumferential pericardial effusion with a hyperdynamic heart that demonstrates diastolic collapse of the right ventricle or right atrium.**

The amount of fluid necessary to cause tamponade typically depends on how rapidly it accumulates. Fluid that collects more slowly will allow the parietal pericardium to expand accordingly and is generally better tolerated (Figure 37-2).¹¹ Pericardial fluid appears as an anechoic collection (Figure 37-3). Small effusions may layer posteriorly or appear as thin black stripes under the pericardium. As effusions increase in volume, they may be seen anteriorly and circumferentially. Pericardial effusions are usually characterized as small, moderate, or large. This is relatively subjective, and grading systems differ. An effusion is considered small if the posterior space measures less than 1 cm, moderate if 1 to 2 cm, and large if more than 2 cm.^{12,13} Loculated effusions are usually spherical or lenticular

FIGURE 37-2. Pressure-volume relationship of the pericardial space. An acute effusion is represented by the solid line. A chronic effusion is represented by the dotted line. (Used with permission from Ma OJ, Mateer JM, Blaivas M: *Emergency Ultrasound*, 2nd ed., McGraw-Hill, 2008.)

collections with echogenic borders and septae. An epicardial fat pad may be confused for pericardial fluid. It can usually be differentiated because it appears as an isolated thin hypoechoic layer. In comparison, the pericardial fluid generally appears anechoic (Figure 37-4).¹⁴

Cardiac US as part of the FAST examination (Chapter 8) has been used to diagnose hemopericardium in the setting of trauma, particularly penetrating injuries.^{2,15} Rozycki et al evaluated the use of US performed by Surgeons, Cardiologists, and Technologists for diagnosing a hemopericardium due to penetrating torso trauma.² This study revealed a sensitivity of 100%, specificity of 96.9%, and accuracy of 97.3%. Plummer et al demonstrated that a rapid sonographic evaluation of the heart performed by EPs expedites lifesaving management for victims of penetrating trauma.¹⁵ Both length of time to operative intervention and mortality were significantly improved by ED cardiac US usage.

ULTRASOUND IN CARDIAC ARREST

Cardiac arrest is the end result of numerous different pathologic states. Sonographic asystole is the absence of ventricular contraction.¹⁶ Rare contractions of the atria and/or mitral valve may

FIGURE 37-3. Free pericardial fluid is visualized as an anechoic stripe surrounding the heart. (Modified with permission from Ma OJ, Mateer JM, Blaivas M: *Emergency Ultrasound*, 2nd ed., McGraw-Hill, 2008.)

FIGURE 37-4. Subcostal long axis view of the heart demonstrating the epicardial fat pad anterior to the right ventricle. The epicardial fat pad is hypoechoic and not anechoic as usually seen with fluid. (Modified with permission from Ma OJ, Mateer JM, Blaivas M: *Emergency Ultrasound*, 2nd ed., McGraw-Hill, 2008.)

continue despite a terminal event. **It is important to base prognosis on ventricular contractions. Ensure that artificial respirations and compressions are held during the US.** Respiratory effort can occasionally appear as ventricular movement. Pulseless electrical activity (PEA) describes the state in which no pulses are palpable but cardiac electrical activity is visible on ECG monitoring. Cardiac activity may or may not be present upon US of a heart in PEA. Cardiac arrest can occur from nonperfusing tachyarrhythmias and bradycardias. Cardiac motion is present in the case of ventricular fibrillation but is unorganized, preventing adequate cardiac filling and ejection of blood. Severe bradycardia causes the heart to beat at a rate too slow to provide adequate perfusion of the heart and other tissues.

US is useful for guiding the management of patients in cardiac arrest. Confirmation of asystole helps the EP in deciding to terminate resuscitation efforts. Blaivas and Fox, in their study of US in cardiac arrest, suggest that patients who arrive to the ED with cardiac standstill on US have little to no chance of survival.⁴

PEA refers to a spectrum of etiologies that can be visualized with US, from subpalpable hypotension with contracting ventricles to terminal erratic cardiac twitches. In an observational study performed by Tayal and Kline, PEA patients without sonographic cardiac activity all died.³ Several patients with sonographic motion of the myocardium had reversible causes such as a pericardial effusion. US has value in diagnosing several other etiologies of PEA, including cardiac tamponade,¹ myocardial infarction,¹⁷ cardiogenic shock,^{5,6} pulmonary embolism (PE),¹⁸ aortic rupture,¹⁹ hypovolemia, and hemorrhagic shock states.²⁰

Circumstance may arise when ventricular fibrillation is not appreciated on the ECG monitor but is diagnosed by US. Fine ventricular fibrillation can look like asystole on the ECG monitor. Ultrasonography of fine ventricular fibrillation appears as rapid trembling of the ventricular myocardium. It appears as a shivering myocardium versus the lack of any motion for asystole.

ULTRASOUND FOR CONGESTIVE HEART FAILURE AND LEFT VENTRICULAR FUNCTION

Congestive heart failure (CHF) is an increasingly common condition that distorts normal cardiac anatomy.²¹ Dilation of the left

ventricle, decreased ejection fraction, and decreased cardiac output are seen in systolic heart failure.²² With a loss of healthy contractility and enlargement of the left ventricle, dilation of the other cardiac chambers generally ensues. Diastolic failure is due to prolonged exposure to high cardiac afterload, as seen with aortic stenosis and uncontrolled hypertension.²³ This results in hypertrophy of the left ventricular myocardium. The thickened myocardium cannot relax appropriately to allow ventricular filling during diastole. Diastolic and systolic heart failure both result in a heart that appears globally enlarged. The point of maximal impulse (PMI) is lateralized due to enlargement of the left ventricle from either dilatation or hypertrophy.

Assessment of left ventricular (LV) function is a fundamental application of the cardiac US. It is particularly useful in the presentation of patients with new-onset CHF. The ability to visualize the LV function allows the EP to better manage the patient presenting with chest pain, dyspnea, or unexplained hypotension. It aids in distinguishing CHF from other causes of dyspnea such as chronic obstructive pulmonary disease, pneumonia, pericardial effusion, and pulmonary embolism.^{24,25}

Moore et al investigated the use of bedside US for estimations of LV function in hypotensive patients.²⁶ It was concluded that EPs with focused cardiac US training can make accurate determinations in comparison to primary Cardiologists for patients with normal and severely depressed ejection fraction. Randazzo et al conducted a study in which EPs performed bedside cardiac US examinations on 115 patients.²⁷ Overall agreement between EP categorization of LV ejection fraction and formal Cardiologist echocardiogram was 86.1%.

Quantitative measurements and complex statistical calculations exist in echocardiography for determining the function of the left ventricle. However, the visual estimate of the global LV function has been shown to be quite accurate.²⁸ Classification of LV function can be simplified into hyperdynamic, normal, mild to moderately depressed, and severely depressed. The more cardiac USs performed, the more comfortable the EP becomes categorizing a patient's LV function. A hyperdynamic heart may suggest hypovolemia or vasodilation and should prompt the EP to volume resuscitate the patient. However, it is imperative to differentiate a hyperdynamic heart from one that is tachycardic with a normal ejection fraction. Hypokinetic contractions appear stiff. Patients with impaired LV function generally have dilated cardiac chambers, limited contractility, and limited inward movement of the ventricular walls during systole (**Figure 37-5**).

FIGURE 37-5. Parasternal long axis view of the heart in a patient with CHF. The enlarged left ventricle has limited contractility and a poor ejection fraction.

FIGURE 37-6. Concern for a PE is raised by the dilatation of the right ventricle. The diameter of the right ventricle is essentially bigger than the diameter of the left ventricle. LA, left atrium; RA, right atrium.

ULTRASOUND FOR PULMONARY EMBOLISM

Bedside US is not sufficiently accurate for the diagnosis of pulmonary embolism (PE) by itself. There are sonographic clues that may help expedite intervention. US is especially helpful in patients with large PEs and hemodynamic compromise that are often too unstable for conventional diagnostic imaging such as computed tomography and ventilation-perfusion scans.

The thin-walled right ventricle (RV) is extremely sensitive to load, and as such, small changes in pressure could lead to large changes in volume. The RV is smaller than the LV. Signs of RV strain include when the RV is noted to be equal or larger than the LV (**Figure 37-6**) or when the RV bows into the LV septum. In the appropriate clinical setting and when combined with other variables, dilation of the RV or RV straining suggests outflow tract obstruction due to PE.^{29,30} Paradoxical bulging of the septum toward the left ventricle during diastolic filling is a sign of right heart strain (**Figure 37-7**).³⁰ **Always keep in mind that numerous other conditions such as emphysema, pulmonary hypertension, and right ventricular infarction**

FIGURE 37-7. Right ventricular dilatation and bulging of the septum into the left ventricle is seen in the presence of a large PE.

could cause right heart strain.^{24,25} RV strain is poorly sensitive for PE but is reasonably specific.³¹ RV strain provides prognostic information in patients with proven PE. The mortality of patients with proven PE and RV strain on US is 10 times the mortality of patients without RV strain.^{30,32} Konstantinides et al showed that hemodynamically stable patients with a proven PE and right heart strain on US findings of right heart dysfunction benefited from thrombolytic therapy.³³ The administration of thrombolytic therapy reduced the need for escalation of treatment but did not affect mortality.³³

ULTRASOUND TO ASSESS UNDIFFERENTIATED SHOCK

The assessment of critical patients with undifferentiated shock is increasingly incorporating information from a number of US applications, including cardiac, inferior vena cava (IVC), thoracic, and FAST images. Cardiac US is one of the most useful studies providing a fast and noninvasive direct view into the cardiovascular problem. A visual picture of the heart and the IVC may quickly establish whether poor perfusion is due to a pump problem (i.e., the heart) or a pipe problem (i.e., the volume). Shock due to heart failure, cardiac tamponade, and PE were described previously. Hypovolemic and distributive shock generally presents with a tachycardic hyperdynamic heart. A variety of algorithms have been proposed for the use of US in the care of the hypotensive patient.^{5,34} There is evidence that the algorithms alter patient management in 78% of the cases.^{34,35} They result in a more focused differential diagnosis and a more accurate ultimate diagnosis for patients in shock.⁶

US evaluation of the IVC provides a surrogate marker of central venous pressures (CVPs) and predicts fluid responsiveness.³⁶ The combined results of the cardiac US and the IVC US can help classify the type of shock and help optimize interventions. Although IVC size does not correlate perfectly with CVP monitor readings, a small and collapsed central vein predicts the need of intravascular volume repletion.³⁷ An IVC diameter of 1.5 to 2 cm is considered normal (**Figure 37-8**).³⁶ A larger IVC indicates elevated CVP. The diameter of the IVC varies with respiration. Negative intrathoracic pressure produced by inspiration causes the IVC to collapse (**Figure 37-9**). A collapse of 50% is considered normal, with greater collapse indicative of low CVP and negligible collapse indicative of high CVP.^{20,36} Simply stated, “fat” great veins are consistent with an elevated CVP and “flat” great veins are consistent with a low CVP. Brief serial examinations during fluid resuscitation can help guide the need for additional fluid.

FIGURE 37-8. The normal caliber of the IVC as it passes beneath the liver in caudal-cephalad direction.

FIGURE 37-9. Longitudinal view of the IVC. **A.** The diameter of the IVC is narrow in this septic patient. **B.** Upon inspiration, the IVC collapses nearly completely (*white arrow*).

INDICATIONS

Cardiac US has been shown to be beneficial in providing diagnostic and prognostic information in the ED (**Table 37-1**). The first described applications for cardiac US were identifying pericardial fluid and evaluation of the cardiac activity.³⁸ These should be the foundation on which further cardiac assessment is built.³⁴ As comfort with those applications improves, more advanced applications can be performed. Those advanced applications include, but are not limited to, the assessment of chest pain, global and left ventricular contractility (i.e., hypercontractile, normal, or decreased), myocardial wall motion abnormalities, RV straining, evidence for PE, assessment of hypotension, and valvular abnormalities (e.g., stenosis, regurgitation, thrombus, or vegetations) (**Figure 37-10**); procedural guidance (e.g., pericardiocentesis and transvenous pacemaker placement); and estimation of CVP by great vein measurements.^{17,39-50} Evaluations for cardiac myxomas, cardiac tumors, septal defects, dynamic function, and pediatric echocardiography are other cardiac US considerations.

TABLE 37-1 Indications for Emergency Cardiac Ultrasonography	
Primary indications	Advanced indications
Cardiac arrest	Cardiac chamber dilation
Pericardial effusion	Cardiac arrest
Traumatic hemopericardium	Cardiac index
	Cardiac tumors
	Chest pain
	Central venous pressure estimates
	Intracardiac thrombus identification
	Hypotension
	Left ventricular function
	Myocardial wall motion defects
	Pediatrics
	Procedural guidance
	Pulmonary embolus
	Septal wall defects
	Shock
	Thoracic aortic dissection
	Valvular dysfunction
	Valvular vegetations
	Ventricular aneurysms
	Wall motion abnormalities

CONTRAINDICATIONS

US is a noninvasive diagnostic modality. It is contraindicated only if it would delay and negatively impact a clinically obvious need for emergent operative intervention. The cardiac US exam should not be performed unsupervised by providers who have not been adequately trained.

EQUIPMENT

- US machine
- US gel
- Phased array low-frequency US probe
- US probe cover or glove

A complete discussion of US equipment is beyond the scope of this chapter. See Chapter 6 for a more complete discussion. Decisions regarding machines and probes depend on the user, cost, and intended applications. The cardiac US exam can be performed with a good-quality, low-frequency probe. Probes with smaller footprints allow for easier viewing between the ribs. The preferred probe for transthoracic imaging is a small-footprint, low-frequency, phased

FIGURE 37-10. An infectious thrombus (*white arrow*) is located on the anterior leaflet of the mitral valve in this parasternal long axis view.

array or microconvex probe (Table 6-2). Curved sequential probes can be used and may produce superior images. The large footprint of these probes can be cumbersome when trying to image between ribs or in a small subxiphoid space.

PATIENT PREPARATION

Little to no preparation is required to perform the cardiac US exam. Wipe any debris and liquids from the patient's skin in the areas to be scanned. Place the US probe in a probe cover or glove if the patient's skin is contaminated with blood, vomit, other body fluids, or other substances that may contaminate or damage the probe.

TECHNIQUES

Echocardiography is a complex field. US is a dynamic tool that is well suited to imaging an organ in motion such as the heart. Much information about cardiac function and flow can be gained from complicated statistical calculation packages, advanced Doppler, and M-mode measurements. This section focuses on the primary views most relevant to the EP with the hope of providing a foundation for more in-depth study of advanced cardiac US techniques in the future.

ORIENTATION INDICATOR

The probe orientation indicator in echocardiography is conventionally set to the right side of the screen. In Radiology, the probe indicator is set to the left side of the screen. Some controversy exists in EM as to which side of the screen to have the probe indicator for cardiac US. Most US machines will set the indicator to the right side of the screen when you choose the cardiac mode, which will flip the screen image 180°. Place the probe with the marker pointing to the patient's left shoulder. However, if you decide to keep the screen marker on the left, as it is in abdominal imaging, then rotate the probe marker 180° to the patient's right hip. **Either way will generate the same image when looking at the screen.** The approach preferred by this author is to set the orientation indicator to the left side of the screen and rotate the probe marker 180°. This orientation will be described here. However, if the other option is preferred, just invert the probe positions described here by 180°.

SUBXIPHOID VIEW

The subxiphoid view is probably the view most commonly used by EPs. It provides visualization of the four heart chambers and allows for a superior evaluation for pericardial fluid (Figure 37-11). It can be performed without interruption of cardiopulmonary resuscitation or the insertion of chest tubes and subclavian central venous lines. The subxiphoid view is often the easiest view to incorporate into the FAST exam. This view can be limited in patients with a protuberant abdomen, abdominal pain, abdominal injuries, free air below the diaphragm, and/or nausea.

Place the probe below the sternum at the costal margin with the probe's marker to the patient's right. The plane of the US probe should be angled to the left chest with the probe pressed nearly flat on the abdomen. Apply a firm amount of pressure to get the US beam below the rib cage (Figure 37-11A). Although the heart lies more to the patient's left, so does the stomach, which contains air that scatters the US beam. It is helpful to move the probe to the right side of the patient and use the liver as an acoustic window into the left chest. Increase the US depth until the posterior pericardial space is completely visualized. Ask the patient to take a deep breath to bring their heart inferiorly and into the scanning plane to improve the image.

A

B

C

FIGURE 37-11. The subxiphoid view. **A.** Patient and probe positioning. **B.** Diagram of the US image. **C.** The US image. LA, left atrium; RA, right atrium. (Used with permission from Ma OJ, Mateer JM, Blaivas M: *Emergency Ultrasound*, 2nd ed., McGraw-Hill, 2008.)

To obtain a complete view of the heart, the US beam depth must be increased beyond that typically used for most other cardiac and abdominal imaging. To grasp the spatial orientation of this view, bear in mind that the probe is aimed from the inferior aspect of the heart. The US beam first traverses the left lobe of

the liver, and hence, liver tissue is seen at the top of the image (**Figures 37-11B and C**). The plane of the beam then slices through the right-sided chambers, the septum, and then the left-sided chambers (**Figures 37-11B and C**). The echogenic pericardium is seen surrounding the myocardium.

PARASTERNAL LONG AXIS VIEW

The parasternal long axis (PSLA) view is usually easier to obtain, provides clearer images, and is better tolerated by the patient. Patients with a heart that is high in the chest or with abdominal distension typically have an excellent PSLA view and a poor subxiphoid view. This is in contrast to patients with hyperinflated lungs (e.g., with chronic obstructive pulmonary disease or on a ventilator) who have a better subxiphoid view than PSLA view.

PSLA view is usually obtained by placing the probe lateral to the sternum in the third or fourth intercostal space (**Figure 37-12A**). The probe marker will be roughly aimed toward the patient's left hip. The PSLA view usually includes the RV, left atrium, mitral valve, LV, and outflow tract (**Figures 37-12B and C**). The RV sits underneath the probe and is visualized in the near field of the screen (**Figures 37-12B and C**). The LV lies beneath the RV. The interventricular septum is well visualized and extends to the apex of the heart on the left side of the screen. The base of the heart can be visualized on the right side of the screen (**Figure 37-12C**). The LV empties into the aortic outflow tract, with the aortic valve and root usually visible. The left atrium lies deep, and the mitral valve can be seen opening into the LV (**Figures 37-12B and C**).

The descending aorta may be visualized in a transverse slice along the underside of the heart and is an important landmark in distinguishing pericardial from pleural fluid. Pleural effusions will taper to the descending aorta, whereas pericardial effusions will cross anterior to the descending aorta. This is due to the fact that the pleura inserts where the descending aorta travels through the thoracic cavity. The pericardium is a self-contained space that crosses the midline (**Figure 37-13**). Pericardial fluid collects posteriorly and will appear as a black stripe separating the myocardium from the pericardium and descending aorta (**Figure 37-13**). Pleural fluid, on the other hand, will reside outside of the bright pericardium and tapers to a stop at the descending aorta.

Adjustments on the tilt of the probe may optimize the view. Place the patient in the left lateral decubitus position, if possible, to bring the heart closer to the chest wall and improve the image. Slide the probe laterally, to a more cephalad intercostal space, or open its rotation with a counterclockwise turn to better optimize the view. Move the probe to a more caudal intercostal space, close the angle of the probe with a clockwise rotation, or use the subxiphoid view to better optimize the view for patients with emphysema and an inferiorly displaced heart.

PARASTERNAL SHORT AXIS VIEW

The parasternal short axis (PSSA) view slices through the heart transversely (**Figure 37-14**). The PSSA view provides an excellent circumferential view of the LV and is often used for the assessment of contractility and regional wall motion abnormalities. Place the probe similar to the PSLA view, but with the probe rotated 90° to rest along the heart's short axis (**Figure 37-14**). Aim the marker toward the patient's right hip. The LV appears as a prominent circle in the center of the screen, with the RV resting atop it as a flatter or crescent-shaped chamber (**Figures 37-14B and 37-15**). Tilting or sliding the probe along the heart's long axis toward the patient's left hip allows visualization of the apex of the heart. Tilting or sliding the probe toward the patient's right shoulder allows visualization of

A

B

C

FIGURE 37-12. The parasternal long axis view. **A.** Patient and probe positioning. **B.** Diagram of the US image. **C.** The US image. Ao, aorta; LA, left atrium. (Used with permission from Ma OJ, Mateer JM, Blaivas M: *Emergency Ultrasound*, 2nd ed., McGraw-Hill, 2008.)

FIGURE 37-13. The parasternal long axis view of a pericardial effusion. Pericardial fluid separates the myocardium from the pericardium and the poorly visualized descending aorta (white arrow).

the base of the heart. The ventricles should cone down to a tip at the apex. When tilting back up from the apex through the heart, the papillary muscles (**Figure 37-15**) and mitral valve with its “fish-mouth” appearance (**Figure 37-16**) will come into view. Continue tilting the probe upward toward the base of the heart. The three leaflets of the aortic valve will be seen centrally (**Figure 37-17**).

APICAL FOUR-CHAMBER VIEW

The apical four-chamber view is typically the most difficult view to obtain. Placing the patient in the left lateral decubitus position will greatly improve the ability to obtain this view by allowing the apex of the heart to be pressed against the left chest. Place the probe at the PMI, just inferior to the nipple and angling up through the heart (**Figure 37-18A**). Aim the probe marker to the patient's right. Alternatively, once you get the PSSA view, slide the probe down to the apex of the heart and tilt it upward toward the base of the heart

to obtain the apical four-chamber view (**Figure 37-18A**). The apical view will show the ventricles side by side in the near field of the screen with the atria in the far field (**Figures 37-18B and C**). The interventricular septum should run vertically down the screen.

The LV appears larger and has thicker walls than the RV. The mitral valve sits slightly lower than the tricuspid valve. Ventricular function, flow across the valves, and septal defects can be assessed with this view. This view allows for comparing chamber size and evaluating for RV dilatation if there is concern for an obstructive PE.

SUBCOSTAL INFERIOR VENA CAVA VIEW

Sonographic evaluation of the IVC can provide valuable hemodynamic information to the EP.²⁰ This view is also referred to as the subxiphoid long axis view. Place the probe in the subxiphoid space, perpendicular to the patient's abdominal wall and with the marker aimed toward the patient's head (**Figure 37-19A**). The longitudinal IVC will appear posteriorly, beneath the liver and the bowel, as a long black cylinder (**Figures 37-19B, C, and D**). **It is important to distinguish the IVC from the aorta.** The aorta lies on the patient's left side, is more “pipe-like” in appearance, is noncompressible when pressure is applied by the US probe, and has a recognizable pulsatility. The IVC is compressible when pressure is applied by the US probe and varies in diameter with respiration (**Figures 37-19C and D**). It may be beneficial to start in the transverse plane in which both the IVC and the aorta are visualized (**Figure 37-20**). Starting with the transverse view, rotate the US probe 90°, maintaining the IVC in the center of the screen to obtain the longitudinal view (**Figure 37-19**). Tilt the probe cephalad to visualize the IVC entering the right atrium (**Figures 37-19C and D**).

Measurements of the IVC proximal to its entrance into the right atrium allow for a noninvasive estimate of CVP. The negative pressure generated in the chest by inspiration draws blood cephalad and decreases the diameter of the IVC (**Figures 37-19C and D**). Normal dimensions for the IVC include a diameter of 1.5 to 2.0 cm and an inspiratory collapse of 50%.²⁰ A smaller diameter and greater inspiratory collapse are indicative of a low CVP.^{20,36} A larger diameter

and lesser inspiratory collapse reflect a high CVP.^{20,36} Obtain estimates by having the patient sniff deeply and freeze the image after inspiration. Use the cine-rewind feature on the US machine to identify images or frames that allow for the measurement of the maximal and minimal IVC diameters through the respiratory cycle (**Figure 37-19**). M-mode tracing of the respiratory cycle allows for precise measures of the inspiratory and expiratory IVC diameters (**Figure 37-21**).

ULTRASOUND GUIDANCE FOR PERICARDIOCENTESIS

US-guided pericardiocentesis has proven to be safe and is the method of choice for most institutions. A brief description of the procedure is provided in this section. Please refer to Chapter 48 for the complete details regarding pericardiocentesis.

Emergent pericardiocentesis can be guided by US using either a static or a dynamic approach. For the static approach, visualize the effusion by US and determine the best approach for needle placement. Remove the probe from the patient and proceed with the pericardiocentesis procedure. For the dynamic approach, the heart is visualized throughout the procedure to guide needle placement. Sterile technique is required for the US probe and cord. The availability of a second ultrasonographer or an assistant for dynamic guidance is helpful, particularly if an agitated-saline injection is attempted.

For the static approach, visualize the path of needle penetration with the corresponding US image. Measure the distance from the top of the image to the pericardial space to determine the depth of needle insertion. It is important to note that the liver is often visualized in the anticipated needle trajectory with the subxiphoid US view.

FIGURE 37-22. US probe and pericardiocentesis needle positioning.

Use the PSLA view because the pericardium is more superficial in this view. Proceed with the pericardiocentesis procedure.

For the dynamic approach, insert the needle directly adjacent to the transducer. Angle the probe to interface with the plane of needle insertion (**Figure 37-22**). Insert the needle over the superior edge of the rib and along the plane of the US beam. It is optional to use color Doppler in the near field to ensure the intercostal and internal mammary arteries are not punctured. Advance the needle while aspirating with the syringe as the needle is advanced. The pericardium may “tent” as the echogenic needle presses upon it (**Figure 37-23A**) and then enters the pericardial space (**Figure 37-23B**).

Injection of agitated saline may be attempted to confirm needle placement in the pericardial space. Agitate the saline by rapidly injecting saline back and forth from one syringe into another through two ports of a three-way stopcock, with the third port connected by sterile tubing to the pericardiocentesis needle. Once microbubbles have formed, inject the agitated saline into the pericardial space. The fluid will appear on US as a bright white scattering within the pericardial sac.

ULTRASOUND GUIDANCE FOR CARDIAC PACING

US can be used to confirm the placement of intracardiac leads or the capture of cardiac pacing (Chapters 41 to 44). It is difficult to appreciate mechanical capture by simply looking for electrical changes on the ECG monitor. Transcutaneous cardiac pacing discharges often cause simultaneous jerking of the patient that masks a palpable pulse. Cardiac US evaluation during cardiac pacing allows visualization of mechanical contractions of the heart. During placement of the transvenous cardiac pacing wire, it can be visualized passing through the right atrium and tricuspid valve into the RV. A subcostal view of the IVC can confirm errant passage of the wire down the IVC.

SUMMARY

Limited ED cardiac ultrasonography provides real-time information to answer specific questions. It is not intended to replace formal cardiac echocardiography. There is a body of evidence that shows that non-Cardiologists can accurately and safely perform limited cardiac US examinations. The use of cardiac US in the ED has risen from a few basic examinations into a sophisticated series of examinations in a very short time. This chapter provided an introduction to ED cardiac ultrasonography. The EP can become very comfortable with cardiac US as a supplement to the evaluation and management of

patients. ED cardiac ultrasonography is a valuable tool that can easily be incorporated into the daily clinical practice of EM.

Chemical Cardioversion

Paul Casey and Thomas Alcorn

INTRODUCTION

Cardioversion is a procedure performed to restore a fast or irregular heartbeat back to normal rhythm.¹ There are two general types of cardioversion. The first is synchronized cardioversion with electricity, which is the most effective treatment.²⁻⁷ The second is pharmacologic or chemical cardioversion. The decision on which type of cardioversion to use is governed by the patient's clinical condition. For unstable patients with hypotension, altered mental status, signs of shock, chest pain, or signs of heart failure, synchronized cardioversion is indicated.²⁻⁴ For patients who are hemodynamically stable without any of the above signs or symptoms, chemical cardioversion may be considered.⁸ The use of chemical cardioversion is less expensive than electrical cardioversion, but patients have more complications.⁹

The specific dysrhythmias for which chemical cardioversion is an option include supraventricular tachycardias (e.g., atrial fibrillation

and atrial flutter) and ventricular tachycardia. This chapter will focus on chemical cardioversion for these tachyarrhythmias.

ANATOMY AND PATHOPHYSIOLOGY

The orchestrated contraction of the atria and ventricles of the heart is the result of an organized electrical impulse passing through the myocytes. This electrical impulse originates in the pacemaker myocytes in the sinoatrial (SA) node in the right atrium and spreads through the atria, resulting in contraction. The impulse arrives at the atrioventricular (AV) node and is subsequently passed down the His bundle and Purkinje fibers to the ventricles, resulting in ventricular contraction. This electromechanical coupling results in approximately 75 mL of oxygenated blood being propelled from the left ventricle into the aorta around 60 to 100 times per minute. A disruption in this sequence may result in cardiac dysrhythmias, which interrupt the delivery of oxygenated blood to vital organs and tissues.

SUPRAVENTRICULAR TACHYCARDIA (SVT)

SVT is an umbrella term that encompasses tachyarrhythmias originating in the atria. These can be further classified into those originating in the atria and those originating from the AV node (Table 38-1).¹⁰ Sinus tachycardia is the most common cause of tachycardia. It is usually an appropriate cardiac physiologic response to an underlying condition (e.g., hypovolemia, anemia, pain, fever, coronary ischemia, pulmonary embolism) and falls outside the scope of this discussion. The most common tachydysrhythmias are AV nodal reentrant tachycardia, AV reentrant tachycardia, atrial fibrillation, and atrial flutter.

AV NODAL REENTRANT TACHYCARDIA (AVNRT) AND AV REENTRANT TACHYCARDIA (AVRT)

AVNRT and AVRT result from the presence of abnormal electrical circuits. In most individuals, the AV node has a single pathway that conducts the impulse in anterograde fashion, resulting in the depolarization of the bundle of His. In some cases, the AV nodal tissue may have two pathways, one that conducts rapidly and one that conducts more slowly. AVNRT is triggered when a premature atrial impulse reaches the AV node while the faster circuit is still refractory from the prior impulse but the slow pathway conducts. That electrical impulse is conducted in a retrograde fashion through the fast circuit, resulting in a recurrent, fast, and simultaneous impulse conduction to the atria and ventricles.

The etiology of the tachydysrhythmia in AVRT is the bypass tract in the cardiac musculature adjacent to the AV node. These bypass tracts may conduct impulses in an anterograde or retrograde fashion and, in some instances, in both directions. When an impulse is conducted down the accessory pathway in an anterograde manner, the result is ventricular preexcitation, which may be clinically evident by the presence of a delta wave on electrocardiogram (ECG). The impulse may then travel in a retrograde manner through the AV node and result in antidromic (from the Greek term meaning “against running”) AVRT. The impulse travels normally down the

AV node and conducts in a retrograde manner through the bypass tract, resulting in orthodromic (from the term meaning “right” or “correct running” in Greek) AVRT. These patterns may be clinically distinguished. The QRS complex of an orthodromic AVRT results in a narrow complex tachycardia, whereas antidromic AVRT results in a wide complex tachycardia.

ATRIAL FLUTTER AND ATRIAL FIBRILLATION

Atrial fibrillation, the most common tachyarrhythmia, is the result of multiple electrical impulses being generated in the atria simultaneously.¹¹ Erratic impulses are conducted through the AV node to the ventricles and result in a rapid ventricular response that manifests on an ECG as an irregularly irregular narrow complex tachycardia. The risk factors for developing atrial fibrillation include older age, male sex, and underlying cardiovascular disease, including hypertension.

Atrial flutter, on the other hand, is the result of a reentrant circuit adjacent to the tricuspid valve in the right atrium. Atrial flutter causes regular impulses from the reentrant circuit in the atrium that manifest on an ECG as an organized regular rhythm. Most commonly, every other atrial impulse is conducted to the ventricles (i.e., 2:1 conduction), resulting in a ventricular rate of 140 to 150 beats per minute. The characteristic flutter waves on the ECG are caused by the regular generation of impulses from the reentrant circuit.

VENTRICULAR TACHYCARDIA

Ventricular tachycardia is most commonly the result of significant underlying heart disease (e.g., hypertrophic cardiomyopathy, dilated cardiomyopathy, coronary artery disease with prior myocardial infarction), although idiopathic ventricular tachycardia is a recognized clinical entity.² The regular coordinated ventricular contractions generated by impulses conducted through the His-Purkinje system are replaced by impulses from a nidus in the ventricle or distal conduction system. The result is ineffective rapid regular or irregular ventricular contractions. The impulses are generated below the AV node, and ventricular tachycardia manifests as a wide complex tachycardia (i.e., QRS interval > 120 milliseconds) on the ECG that may be regular or irregular.

INDICATIONS

Chemical cardioversion is indicated when a restoration of normal sinus rhythm is needed. Chemical cardioversion is only indicated in the stable patient. A stable patient will have a pulse and no evidence of hemodynamic compromise (e.g., hypotension, altered mental status, chest pain, or heart failure) other than a rapid heart rate. For the stable patient in atrial fibrillation or atrial flutter, the decision to chemically cardiovert to sinus rhythm versus rate control depends on the duration of symptoms, symptom severity, age, preexisting heart disease, and underlying medical conditions.^{6,12} These decisions are often outside the scope of Emergency Medicine and best made in consultation with a Cardiologist. One may consider chemical cardioversion in a stable patient with both SVTs and ventricular tachycardias. The patient may prefer chemical cardioversion to electrical cardioversion. The advantages of chemical cardioversion are that it does not require the patient to be fasted, it is painless, and it does not require the administration of anesthesia.

CONTRAINDICATIONS

Chemical cardioversion is not indicated in unstable patients with signs or symptoms of hypoperfusion or patients without a pulse (e.g., pulseless ventricular tachycardia or ventricular fibrillation).²

TABLE 38-1 The Common Supraventricular Tachycardias¹⁰

Atrial tachyarrhythmias	AV tachyarrhythmias
Atrial fibrillation	AV nodal reentrant tachycardia
Atrial flutter	AV reentrant tachycardia
Multifocal atrial tachycardia	Junctional ectopic tachycardia
Sinus nodal reentrant tachycardia	
Sinus tachycardia	

Electrical cardioversion remains the treatment of choice.²⁻⁷ Chemical cardioversion of atrial fibrillation or atrial flutter should only be considered when the duration of the atrial dysrhythmia is known and is less than 48 hours or if the patient has been anticoagulated for the appropriate duration prior to attempting chemical cardioversion.¹³ This decision is commonly made in consultation with a Cardiologist.

EQUIPMENT

- Noninvasive blood pressure monitor
- Heart rate monitor
- Pulse oximeter
- Cardiac monitor
- Intravenous access supplies (Chapters 59 and 61)
- Supplemental oxygen
- Bag-valve mask
- Suction device
- Intubation equipment (Chapter 18)
- Medications for chemical cardioversion
- Code cart with advanced cardiac life support (ACLS) medications
- ECG machine for continuous 12-lead ECG

ADENOSINE

Adenosine is an endogenous nucleoside occurring in all cells of the body.^{11,14} Each milliliter of adenosine for injection contains 3 mg of adenosine and 9 mg of sodium chloride in water. The pH of the solution is between 4.5 and 7.5. The intravenous bolus dose usually has no systemic hemodynamic effects.

Adenosine slows the conduction time through the AV node, can interrupt the reentry pathways through the AV node, and can restore normal sinus rhythm in patients with paroxysmal supraventricular tachycardia (PSVT) and PSVT associated with Wolff-Parkinson-White syndrome.¹⁰ Adenosine is antagonized competitively by methylxanthines (e.g., caffeine and theophylline). Larger doses of adenosine may be required, or adenosine may not be effective. The effect of adenosine is potentiated by blockers of nucleoside transport (e.g., dipyridamole). Smaller doses of adenosine may be effective. Adenosine is not effective in converting rhythms other than PSVT (e.g., atrial flutter, atrial fibrillation, or ventricular tachycardia) to normal sinus rhythm.

Intravenously administered adenosine is rapidly cleared from the circulation via cellular uptake. Intracellular adenosine is rapidly metabolized via phosphorylation to adenosine monophosphate by adenosine kinase or via deamination to inosine by adenosine deaminase in the cytosol. Inosine formed by deamination of adenosine can leave the cell intact or can be degraded to hypoxanthine, xanthine, and ultimately uric acid. Adenosine monophosphate formed by phosphorylation is incorporated into the high-energy phosphate pool. Adenosine requires no hepatic or renal function for its activation or inactivation.

Intravenous adenosine injection is contraindicated in patients with second- or third-degree AV block, sinus node disease (e.g., sick sinus syndrome or symptomatic bradycardia), or a known hypersensitivity to adenosine.

At the time of conversion to normal sinus rhythm, a variety of rhythms may appear on the ECG. They usually last only a few seconds without intervention. These include premature ventricular contractions, atrial premature contractions, atrial fibrillation, sinus bradycardia, sinus tachycardia, skipped beats, and varying degrees of AV nodal block.

Adenosine exerts its effect by decreasing conduction through the AV node and may produce a short-lasting first-, second-, or third-degree heart block. The very short half-life of adenosine allows these effects to be self-limiting. **Administer treatment for these rhythms if they are prolonged. Do not administer additional doses if a high-level block occurs with a dose of adenosine.** Higher degrees of heart block may be produced in the presence of carbamazepine. Transient or prolonged episodes of asystole have been reported with fatal outcomes. Use adenosine with caution in patients receiving digoxin or the combination of digoxin and verapamil to prevent complete heart block and ventricular fibrillation.

No controlled studies have been conducted in pediatric patients to establish the safety and efficacy of adenosine for the conversion of PSVT. However, intravenous adenosine has been safely used for the treatment of PSVT in neonates, infants, children, and adolescents.

Adenosine injection should be given as a rapid bolus by peripheral intravenous (IV) injection into a vein or an IV line as close to the heart as possible, followed by a rapid saline flush.

AMIODARONE

Amiodarone is a class III antiarrhythmic drug.^{11,14} Each milliliter of amiodarone for injection contains 50 mg of amiodarone hydrochloride, 20.2 mg of benzyl alcohol, 100 mg of polysorbate 80, and water.

Amiodarone is considered a class III antiarrhythmic drug but possesses the electrophysiologic characteristics of all four antiarrhythmic classes. It blocks sodium channels at rapid pacing frequencies, exerts a noncompetitive antisymphathetic action, lengthens the cardiac action potential, and has negative chronotropic effects in nodal tissues. Amiodarone also blocks myocardial potassium channels, which contributes to a slowing of conduction and prolongation of the refractory period. The antisymphathetic action, block of calcium channels, and block of potassium channels are responsible for the negative dromotropic effects on the sinus node and for the slowing of conduction and prolongation of the refractory period of the AV node. Its vasodilatory action can decrease cardiac workload and myocardial oxygen consumption.

Administration of amiodarone prolongs intranodal conduction and the refractory period of the AV node. It has little or no effect on sinus cycle length, refractory period of the right atrium and right ventricle, repolarization (i.e., QTc), intraventricular conduction (i.e., QRS interval), and infranodal conduction. Administer amiodarone for acute treatment until the ventricular arrhythmias are stabilized.³ Most patients will require therapy for 48 to 96 hours.

Amiodarone is metabolized to desethylamiodarone (DEA) by the cytochrome P450 (CYP450) enzyme group, specifically CYP3A4 and CYP2C8. The CYP3A4 isoenzyme is present in both the liver and intestines. The highly variable systemic availability of oral amiodarone may be attributed to the large interindividual variability in CYP3A4 activity. Amiodarone is an inhibitor of CYP3A4 and P-glycoprotein. It has the potential for interactions with drugs or substances that may be substrates, inhibitors, or inducers of CYP3A4 and substrates of P-glycoprotein. Examples include protease inhibitors, histamine H₁ and H₂ antagonists, antidepressants, immunosuppressives, HMG-CoA drugs, cardiac glycosides, other antiarrhythmics, anticoagulants, and others. **It is suggested to look up the interactions with other medications before using amiodarone.**

Amiodarone is primarily eliminated by hepatic metabolism and biliary excretion. There is negligible excretion of amiodarone or DEA in urine. Neither amiodarone nor DEA is dialyzable. Amiodarone and DEA cross the placenta, and both appear in breast milk.

No data are available on the activity of DEA in man. It has a significant electrophysiologic and antiarrhythmic effects in animals

similar to amiodarone. DEA's role and contribution to the antiarrhythmic activity of oral amiodarone are not certain. There is evidence of amiodarone activity before significant concentrations of DEA are attained.

Amiodarone is contraindicated in patients with known hypersensitivity to any of the components, an allergy to iodine, cardiogenic shock, marked sinus bradycardia, and second- or third-degree AV block unless a functioning pacemaker is available.

Hypotension is the most common adverse effect of amiodarone. **Clinically significant hypotension is related to the rate of infusion and not the dose.** Treat hypotension by slowing the infusion. Additional therapy may include IV fluids, positive inotropes, and vasopressors. Other side effects include bradycardia, AV block, elevated liver enzymes, worsening of existing arrhythmias, precipitation of a new arrhythmia (e.g., torsades de pointes), acute eye problems, thyrotoxicosis, hyperthyroidism, and hypothyroidism. The combination of amiodarone with other antiarrhythmic agents that prolong the QTc interval should be reserved for patients with life-threatening ventricular arrhythmias incompletely responsive to a single agent. Do not use amiodarone with other drugs that prolong the QTc interval (e.g., fluoroquinolones) unless life-threatening arrhythmias occur.

PROCAINAMIDE

Procainamide hydrochloride is an old antiarrhythmic agent.^{11,14} Each milliliter of procainamide for injection contains 500 mg of procainamide, 1 mg of methylparaben, 1.8 mg of sodium metabisulfite, and water. It has a pH of 4.0 to 6.0. Procainamide hydrochloride is a class IA cardiac antiarrhythmic drug.

Procainamide increases the effective refractory period of the atria and, to a lesser extent, the His-Purkinje system and ventricles of the heart. It reduces impulse conduction velocity in the atria, His-Purkinje fibers, and ventricular muscle. It has variable effects on the AV node with a direct slowing action and a weaker vagolytic effect. The myocardial excitability is reduced in the atria, Purkinje fibers, papillary muscles, and ventricles by an increase in the threshold for excitation combined with inhibition of ectopic pacemaker activity by slowing the slow phase of diastolic depolarization. This decreases automaticity in ectopic sites. Contractility of the undamaged heart is usually not affected.

Therapeutic levels of procainamide may exert vagolytic effects and produce a slight acceleration of the heart rate. High or toxic concentrations may prolong AV conduction time, cause an AV block, or cause abnormal automaticity. The ECG may show a slight sinus tachycardia due to the anticholinergic action, widened QRS complexes, prolonged QT and PR intervals due to longer systole and slower conduction, and a decrease in QRS and T-wave amplitude.

Administration of procainamide can produce therapeutic levels within minutes after the infusion is started. Approximately 20% is reversibly bound to plasma proteins. It binds more slowly and reversibly to the heart, liver, lungs, and kidney. A significant fraction of the circulating procainamide may be metabolized in hepatocytes to *N*-acetylprocainamide (NAPA). NAPA has significant antiarrhythmic activity and slower renal clearance than procainamide. Hepatic acetylation rate capability, renal function, and age have significant effects on the effective biologic therapeutic action.

Procainamide is indicated for the treatment of ventricular arrhythmias (e.g., sustained ventricular tachycardia).^{2,15} Its use with lesser arrhythmias is not recommended due to its proarrhythmic effect. **Do not treat patients with premature ventricular contractions.**

Side effects are common. **Procainamide has the potential to produce serious hematologic disorders. This includes fatal leukopenia or agranulocytosis.** Do not administer procainamide to

patients with complete heart block because it can suppress nodal pacemakers, suppress ventricular pacemakers, and cause asystole. It may be difficult to recognize complete heart block in patients with ventricular tachycardia. Significant ventricular slowing without evidence of AV conduction appearing during procainamide administration is a reason to stop the infusion. **Do not administer procainamide to patients with second-degree AV block or hemiblocks due to the possibility of increased block severity unless the patient has an electrical pacemaker.** Avoid procainamide if the patient is sensitive to procaine or other ester-type local anesthetics. **Procainamide is contraindicated in patients with torsades de pointes.** Procainamide may aggravate this condition instead of suppressing it.

The National Heart, Lung, and Blood Institute's Cardiac Arrhythmia Suppression Trial (CAST) was a long-term, multicenter, randomized, double-blind study in patients with asymptomatic non-life-threatening ventricular arrhythmias who had a myocardial infarction more than 6 days but less than 2 years previously. Excessive mortality or nonfatal cardiac arrest was seen in patients treated with encainide or flecainide. These results and the lack of evidence of improved survival for any antiarrhythmic drug in patients without life-threatening arrhythmias resulted in a warning to not use procainamide in patients with non-life-threatening ventricular arrhythmias.

Monitor the patient's blood pressure during administration of procainamide. It can cause significant hypotension.² Use caution to avoid rapid administration of procainamide. Stop the infusion temporarily if the blood pressure decreases by 15 mmHg or more. ECG monitoring is recommended for observation of the response to treatment and detection of QRS complex widening, prolongation of the PR interval, or any signs of heart block.

SOTALOL

Sotalol hydrochloride is an antiarrhythmic drug with class II (β -adrenoceptor blocking) and class III (cardiac action potential duration prolongation) properties.^{11,14} It can cause life-threatening ventricular tachycardia associated with QT interval prolongation.

Sotalol is used for the treatment of life-threatening ventricular arrhythmias and the maintenance of normal sinus rhythm in patients with atrial fibrillation or atrial flutter. It should not be used in patients with premature ventricular contractions and those with minimally symptomatic or easily reversible atrial fibrillation or atrial flutter. Other contraindications to the use of sotalol include sinus bradycardia, second-degree AV block, third-degree AV block, sick sinus syndrome, congenital or acquired long QT syndrome, serum potassium < 4 meq/L, cardiogenic shock, decompensated heart failure, asthma or other bronchospastic conditions, prolonged QT interval > 450 milliseconds, and a creatine clearance < 40 mL/min.

Sotalol can cause QT prolongation, bradycardia, AV block, hypotension, and worsening heart failure. Do not abruptly reduce the dose or discontinue the sotalol due to acute exacerbation of coronary artery disease upon cessation of therapy. The sotalol may mask symptoms of hypoglycemia or worsen hyperglycemia in diabetic patients. Avoid its use with other antiarrhythmics or drugs that prolong the QT interval. Avoid using sotalol with digoxin and calcium channel blockers due to the increased risk of bradycardia, hypotension, and heart failure.

The use of sotalol in any age group with decreased renal function should be at lower doses or increased intervals between doses. The normal starting dose is 80 mg twice a day.³ Closely monitor heart rate and QTc interval. Dose escalations in renal impairment should be done after administration of multiple doses at appropriate intervals. Sotalol is partly removed by dialysis.

IBUTILIDE

Ibutilide fumarate is an antiarrhythmic drug with predominantly class III cardiac action potential prolongation properties.^{14,16} Each milliliter of ibutilide for injection contains 0.1 mg of ibutilide fumarate (which is equivalent to 0.087 mg of ibutilide free base), 0.189 mg of sodium acetate trihydrate, 8.90 mg of sodium chloride, hydrochloric acid to adjust the pH to approximately 4.6, and water.

Ibutilide prolongs the action potential duration in isolated adult cardiac myocytes and increases the atrial and ventricular refractory periods. Ibutilide delays repolarization by the activation of a slow inward current of predominantly sodium. Most class III antiarrhythmics block outward potassium currents. These effects lead to prolongation of atrial and ventricular action potential duration and the refractory period. Ibutilide produces mild slowing of the sinus rate and AV conduction. There is no clinically significant effect on QRS duration at IV doses up to 0.03 mg/kg administered over 10 minutes. There is no established relationship between plasma concentration and antiarrhythmic effect. Ibutilide produces a dose-related prolongation of the QT interval. It has no clinically significant effects on cardiac output, mean pulmonary arterial pressure, or pulmonary capillary wedge pressure at doses up to 0.03 mg/kg.

Ibutilide has a high systemic plasma clearance that approximates liver blood flow (about 29 mL/min/kg), a large steady-state volume of distribution (about 11 L/kg), and minimal (about 40%) protein binding. It is cleared rapidly and highly distributed in patients being treated for atrial flutter or atrial fibrillation. The pharmacokinetics in patients with atrial flutter or atrial fibrillation are similar regardless of the type of arrhythmia, patient age, sex, or the concomitant use of digoxin, calcium channel blockers, or beta-blockers. Most is excreted in the urine, with about 7% of the dose excreted as unchanged ibutilide and the remainder (about 19%) excreted in the feces.

Ibutilide is indicated for the rapid conversion of atrial fibrillation or atrial flutter of recent onset to sinus rhythm.^{3,16} Patients with atrial arrhythmias of longer duration are less likely to respond to ibutilide. Ibutilide is indicated for rapid IV therapy of ≤ 30 minutes. It is dosed to the termination of the arrhythmia or to a maximum of two doses of 0.01 mg/kg up to a maximum of 1 mg per dose over 10 minutes. Its use can cause potentially fatal arrhythmias (e.g., sustained polymorphic ventricular tachycardia and torsades de pointes). **It is essential that ibutilide be administered in a setting of continuous ECG monitoring and by personnel trained in identification and treatment of acute ventricular arrhythmias. Patients with atrial fibrillation of more than 2 to 3 days in duration must be adequately anticoagulated before conversion with ibutilide so they do not throw a clot and have a stroke.**

Ibutilide is contraindicated in patients who have previously demonstrated hypersensitivity to ibutilide or any of the other components. Ibutilide can induce or worsen ventricular arrhythmias with fatal consequences. Torsades de pointes may occur because of ibutilide's effect on cardiac repolarization, or it can cause ventricular tachycardia in the absence of excessive prolongation of the QT interval. Antiarrhythmics should not be given concomitantly with ibutilide or within 4 hours after infusion because of their potential to prolong the refractory period. Ibutilide can cause heart block. Use caution in patients whose plasma digoxin levels are above or suspected to be above the therapeutic range. Ibutilide should not be administered to pregnant women and those who are breastfeeding.

MISCELLANEOUS AGENTS

The patient is sometimes given dofetilide, dronedarone, mexiletine, or propafenone to convert atrial fibrillation or atrial flutter.^{11,14,17} These agents are all administered orally and titrated to effect or

side effects. These medications are usually not administered in the Emergency Department and not covered in this chapter.

PATIENT PREPARATION

Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Obtain an informed consent for the procedure, and place this in the medical record.

Ensure the patient is stable with a pulse. They should have no hypotension, altered mental status, signs of shock, ischemic chest discomfort, or acute heart failure. Place the crash cart in the room. Apply pads to the patient if a stable rhythm deteriorates into an unstable rhythm. Fully monitor the patient. Apply a noninvasive blood pressure cuff, cardiac monitor, and pulse oximetry. Obtain venous access. Apply a nasal cannula attached to wall oxygen.

Obtain a 12-lead ECG and identify the rhythm. The first important distinction when interpreting the ECG is whether the QRS interval is wide (i.e., > 0.12 seconds) versus narrow (i.e., < 0.12 seconds). **The cause of a wide complex tachycardia is ventricular tachycardia until proven otherwise.**⁸ The differences between SVT with a wide QRS complex due to aberrancy or preexcitation versus ventricular tachycardia are nuances and represent a diagnostic challenge.⁸ The 12-lead ECG may help distinguish the different rhythms. Discern if the rhythm is regular or irregular and if it is monomorphic or polymorphic. Determining the rhythm will dictate which medication to use for the chemical cardioversion.

TECHNIQUES

NARROW COMPLEX TACHYCARDIA

This SVT is not due to sinus tachycardia. Consider vagal maneuvers (e.g., unilateral carotid massage) first to see if the patient converts to a sinus rhythm. This may or may not work. Administer adenosine next by rapid IV push over 1 to 2 seconds through a peripheral IV as proximal to the heart as possible. This is due to the very short half-life of adenosine. The IV should be ideally placed in the upper arm. The recommended approach to ensure rapid administration is with a T-connector or stopcock with the normal saline flush and adenosine connected.

The initial dose is 0.1 mg/kg to a maximum dose of 6 mg. Immediately follow the adenosine with a rapid 10 mL flush of normal saline. Observe the monitor for a pause followed by the conversion to a normal sinus rhythm. The adenosine may be repeated at 0.2 mg/kg to a maximum of 12 mg and 0.3 mg/kg to a maximum of 18 mg. Slowing the rate for a brief time with adenosine allows the underlying rhythm to be identified. This may lead to the treatment for atrial fibrillation or atrial flutter.

MONOMORPHIC VENTRICULAR TACHYCARDIA

Evidence suggests IV adenosine is relatively safe for the diagnosis and treatment of ventricular tachycardia that is monomorphic and regular. Administer adenosine as described above. Emergency Physicians usually and immediately administer amiodarone given the familiarity with it in the unstable patient with shock-resistant ventricular tachycardia. However, multiple drug options are available. Amiodarone was previously the American Heart Association's (AHA) antiarrhythmic of choice for patients in ventricular tachycardia. This was based on expert opinion rather than evidence. **The 2015 AHA guidelines list amiodarone, procainamide, and sotalol as options.** Avoid procainamide and sotalol in patients with a prolonged QT interval and heart failure. A second agent should not be given after procainamide or sotalol without an expert consultation

(e.g., a Cardiologist or Electrophysiologist) per the 2015 AHA guidelines. Recent studies have suggested procainamide has increased efficacy and decreased side effects when compared to other antiarrhythmics. More research needs to be done on this subject. Lidocaine is no longer included in the AHA guidelines for management of wide complex tachycardias.

The doses of the medications are quite different. Administer IV procainamide at 20 to 50 mg/min over 10 to 20 minutes or 100 mg every 5 minutes until resolution of ventricular tachycardia, occurrence of side effects, or a maximum of 17 mg/kg.^{2,4} Administer 150 mg of amiodarone IV over 10 minutes, followed by 1 mg/min for 6 hours, and then 0.5 mg/min for at least 18 hours. Administer sotalol at 1.5 mg/kg IV over 5 minutes.

POLYMORPHIC VENTRICULAR TACHYCARDIA

Administer IV magnesium if the patient is known to have prolonged QT syndrome or a prolonged QT interval is observed on ECG review when the patient was in sinus rhythm. Use the dose of 1 to 2 gm of magnesium over 5 to 60 minutes. The most common etiology of polymorphic ventricular tachycardia is myocardial ischemia in the absence of a prolonged QT interval. Administer amiodarone and beta-blockers because magnesium is likely to be ineffective. Consult a Cardiologist for further recommendations and management.

ATRIAL FIBRILLATION OR FLUTTER

Administer amiodarone, ibutilide, or sotalol for atrial fibrillation or atrial flutter.¹⁸ Consider consulting a Cardiologist first. Structural heart disease often prevents the chemical cardioversion or causes the reversion of normal sinus rhythm to the preceding rhythm.^{5,17} The Cardiologist may use a combination of medications to control the rate or rhythm before later attempting electrical cardioversion.^{3,19,20} This combination therapy is not performed in the Emergency Department.

AFTERCARE

Obtain a 12-lead ECG and a repeat set of vital signs.⁴ Consult an Interventional Cardiologist if there is any evidence of cardiac ischemia. Correct any underlying causes (e.g., electrolyte abnormalities). Consult a Cardiologist or Electrophysiologist for further evaluation. Disposition varies depending on the etiology and type of arrhythmia.^{1,5,21-23} Most patients will be admitted for cardiac monitoring, evaluation of the arrhythmia, and treatment of any underlying causes.⁵

COMPLICATIONS

The most worrisome complication during chemical cardioversion is the conversion into an unstable arrhythmia. This can be due to the medications given or a progression of the preexisting dysrhythmia. **It is important to be prepared and ready to initiate electrical cardioversion or cardiopulmonary resuscitation.**

Medication complications are specific to the medications administered to the patient. Many of these medications may precipitate hypotension. A review of all the medication-related complications is beyond the scope of this chapter. Some of the common medication-related complications were noted previously. Amiodarone can cause bradycardia, hypotension, or pulmonary toxicity, or worsen the dysrhythmia. Procainamide can cause bradycardia and hypotension, increase the QRS duration over 50%, and worsen the dysrhythmia. Sotalol can cause dose-related bradycardia, chest pain, and fatigue.

SUMMARY

The Emergency Physician must rapidly identify and treat patients who are hemodynamically unstable or symptomatic due to an arrhythmia. These patients are not candidates for chemical cardioversion and should receive electrical cardioversion (Chapter 40). The goal of chemical cardioversion is the restoration of a normal sinus rhythm in stable patients with a pulse. The pharmacologic management of chemical cardioversion varies depending on the underlying rhythm.

Automated External Defibrillation

James Montoya and Molly Garcia

INTRODUCTION

Cardiovascular disease is the most common cause of death in the developed world. It is responsible for 350,000 deaths per year in the United States.¹ Approximately 40% of those with out-of-hospital cardiac arrest (OOHCA) have an initial presenting rhythm of ventricular fibrillation.² Early defibrillation increases the chances of survival in these situations.

The American Heart Association (AHA) undertook a program in 1991 dedicated to increasing the rate of survival from OOHCA with education regarding the concept of a “chain of survival.”³ The chain is a series of actions that give the highest chances of survival. The links of the chain include calling 911, performing early cardiopulmonary resuscitation (CPR), providing rapid defibrillation, and survival. Inherent are the concepts of early defibrillation and “time is muscle.”

The AHA had further advocated in 1995 the use of automated external defibrillators (AEDs) by laypersons as a key link in the chain (**Figure 39-1**).² This allowed all but early advanced life support by laypersons. The AED automatically analyzes the heart rhythm and delivers an electrical shock to restore the heart to a normal rhythm.⁴

Most cardiac arrests occur outside the hospital. Ventricular fibrillation is the most common rhythm in OOHCA. There has been a concerted effort in the United States to increase the availability of AEDs in public spaces (e.g., airports, casinos, stadiums) and to responding police officers, resulting in a much higher survival in ventricular fibrillation arrest.⁵⁻¹¹ The approximate 10% survival rate after OOHCA and in-hospital sudden cardiac arrest remains dismally low.¹² The rates versus historical norms in bystander-witnessed ventricular fibrillation arrest have been much improved to as high as 31% in some studies by this effort.^{13,14}

Health care professionals often use traditional manual defibrillators (Chapter 40). These are not widely available outside of the hospital. The Emergency Physician must interpret the heart rhythm, know when cardioversion or defibrillation is appropriate, and manually operate the defibrillator. A thorough understanding of how to properly operate AEDs is important. Some AEDs switch modes to become manual defibrillators.

ANATOMY AND PATHOPHYSIOLOGY

The heart is composed of two systems, a physical pump driven by the rhythmic discharge of the electrical system. The electrical system is a conduit composed of the sinus node, the atrioventricular node, the bundle of His, and the left and right bundle branches (**Figure 39-2**). There is an intrinsic regular electrical discharge

originating in the sinus node propagating toward the left ventricle in normal sinus rhythm. This electrical discharge has an effective vector from the sinus node toward the left ventricle. Disruptions in this system or dysfunction of the sinus node leads to abnormal electrical activity or an arrhythmia.

Cardioversion and defibrillation are different. Cardioversion is the process of using synchronized (i.e., during the R-wave or QRS complex) electrical shock to interrupt and terminate the abnormal electrical activity, allowing the sinus node to resume its normal activity. Defibrillation uses unsynchronized (i.e., any time during the cardiac cycle) electrical shock. Several dysrhythmias have been demonstrated to be amenable to cardioversion or defibrillation (e.g., atrial fibrillation with rapid ventricular rate, supraventricular tachycardia, and stable ventricular tachycardia). **Ventricular tachycardia and ventricular fibrillation are the only two cardiac rhythms in which shock is signaled as “indicated” and defibrillation is recommended by an AED.**

INDICATIONS

The use of an AED is indicated in patients who have suffered collapse, are unresponsive, or are in cardiac arrest.¹⁵⁻²⁰ Patients are often positioned in places of high public traffic and areas of congregation (e.g., airports, concert arenas, and stadiums). First responders (e.g., firefighters and police officers) carry AEDs as standard equipment in some areas. **The application of the AED is indicated in anyone who has collapsed.** The AED will recommend “shock” in patients if ventricular fibrillation or ventricular tachycardia is detected.²¹

CONTRAINDICATIONS

Only apply AEDs to patients who are in cardiac arrest and/or unconscious. Do not apply the AED to patients who are breathing, are conscious, or have palpable pulses. AEDs will identify ventricular tachycardia to be a shockable rhythm even if the patient is alert and the rhythm may be amenable to chemical cardioversion.¹⁴ Other rhythms seen in cardiac arrest are pulseless electrical activity (PEA) and asystole. Administration of a shock when the patient is in PEA is not indicated since the electrical activity of the heart is already organized. Shocking a patient in asystole will have no effect since there is no electrical activity of the heart to reset. An AED can be applied to these patients. The AED will determine that a shock is not indicated when these rhythms are detected. Do not use an AED to monitor the heart rhythm if a cardiac monitor is not available.

Medications may sensitize the heart to an electrical stimulus. Some medications may increase the amount of electricity required to defibrillate patients, while others may decrease the energy requirement.²² Carefully consider defibrillation versus alternate therapies (e.g., Digibind) in patients known to take digitalis or its derivatives.²³

EQUIPMENT

- AED device (**Figure 39-1**)
- Two self-adhesive electrode pads (**Figure 39-3**)
- Razors, if available but may not be necessary
- Trauma shears or scissors for clothing removal

AED CLASSIFICATION

AEDs are classified as semiautomatic, fully automatic, monophasic, and biphasic.²⁴ Some AEDs can switch to manual mode. Semiautomatic AEDs are the most common type. The user must push a button on the AED to deliver the shock. Another name for these

FIGURE 39-1. Examples of some of the many AEDs commercially available. **A.** Physio-Control Lifepak CR Plus. **B.** Zoll Pro Semi-automatic. **C.** Cardiac Science Powerheart G3. **D.** Samaritan HeartSine 450P.

AEDs are shock advisory defibrillators. Fully automatic AEDs do not require the press of a button to deliver a shock. The AED delivers the shock automatically. Fully automatic AEDs are available in the United States from many different manufacturers, each with somewhat different evaluative algorithms.

Many AEDs are monophasic.^{25,26} They are slowly being replaced with biphasic AEDs.^{25,26} Monophasic AEDs deliver one shock from the negative electrode to the positive electrode when a shock is indicated. The amount of energy delivered during a monophasic shock is generally between 200 and 360 J.²⁷ Biphasic AEDs send a shock from the negative electrode to the positive electrode and then in the reverse

direction (**Figure 39-4**). Biphasic AEDs can measure the impedance and resistance between the electrodes and adjust how much energy is used. This allows the AED to deliver enough energy needed to reset the heart but not enough to damage the heart. Energy levels typically range between 120 and 200 J.²⁷ Less battery life is needed with biphasic AEDs since they deliver less energy per shock. Biphasic AEDs provide a more consistent magnitude of current and tend to successfully terminate arrhythmias at lower energies than monophasic AEDs, although neither monophasic nor biphasic AEDs lead to a survival advantage over the other.²⁸⁻³⁰ Biphasic AEDs are smaller and easier to carry or store in areas outside of the hospital.

FIGURE 39-2. Conduction system of the heart. (Used from <https://commons.wikimedia.org>.)

PATIENT PREPARATION

Assess the cardiac, neurologic, and respiratory status of the patient. Start with basic life support care. Place the patient supine on a flat hard surface and initiate CPR. Initiate a search to identify the availability of an AED nearby. Open or cut the patient's shirt to expose skin. Some AEDs have a lid that can be placed under the patient's shoulders to optimize airway opening. Activate 911 and continue

CPR if it is determined that cardiac output is insufficient to oxygenate the brain and vital organs.

AEDs are designed for safe and correct operation by the layperson (**Table 39-1**). Directions are generally on the unit in universal

FIGURE 39-3. An example of AED pads. Note each pad has a picture of placement in the adult and child. (Used from <https://commons.wikimedia.org>.)

FIGURE 39-4. Biphasic AEDs produce shocks in both directions. Monophasic AEDs only shock in one direction (not shown). (Used from <https://commons.wikimedia.org>.)

TABLE 39-1 AED Precautions

AEDs can cause harm
Analyze the rhythm without CPR
Change batteries annually
Check the electrode wires for cracks regularly
Do not place AED patches over implanted defibrillators
Do not place AED patches over medication patches
Do not use the AED in seizing patients
Dry off the chest
Have maintenance performed on the AED annually
Liability is waived in most states for bystanders using AEDs
Make sure the AED is programmed for the most current AHA guidelines
Patients must be pulseless
Patients must be unconscious
Patients must be unstable
Periodically check to see if the AED is recalled
Remove the patient from wet environments
Stop transporting when checking rhythms
Use the AED with caution in moving vehicles

pictogram form (Figure 39-5). Directions may be delivered by the unit via voice command. The emergency dispatchers at 911 can guide the layperson with little or no previous training with the use of the AED in an emergency.¹³

TECHNIQUE

Turn on the AED. Most AEDs provide audio or visual prompts that will instruct the user of the next steps. Attach the adhesive electrodes of the AED. The adhesive electrodes (“pads”) detect the cardiac rhythm. The right pad is placed to the chest wall just below the right clavicle. The left pad is placed lateral to the left breast or apically in position (Figures 39-3, 39-4, and 39-5). Additional acceptable placement of pads includes placement in the standard anterior-posterior configuration or in a bi-axillary position (Figures 40-6 and 40-7).³¹ Individual manufacturers may have guidelines regarding proper pad placement, and this

FIGURE 39-5. Universal pictogram on an AED.

information is usually found in the pictogram or on the packaging (Figure 39-5). **Place the pads at least 2.5 cm away from implanted devices and not on top of any transdermal medication patches as they can interfere with the shock delivered and burn the skin.**³² **Do not use the AED if the pads touch each other when attached to the patient.**³²

The chest hair needs to be removed if it does not allow for thorough adhesion of the pads to the chest. Quickly shave the torso hair with a razor if the electrodes do not stick.³² Alternatively, place an extra pad in the correct position and rapidly pull the pad away from the skin, causing the hair to be removed, if extra AED pads are available. Replace the hair-containing pad with a fresh new pad.

It is necessary to observe if the material surrounding the patient will conduct electricity to the rescuer prior to initiation of rhythm analysis. This includes water or metal. Dry any wetness on the chest or remove the patient from wet environmental conditions. Ensure that no one is touching the metal if the patient is on metal when the shock is delivered.³²

Begin rhythm analysis by turning the AED on if it is fully automatic or turning it on and pressing the “analyze” button. **Do not touch the patient during rhythm analysis. It can interfere with the computer algorithm used to analyze the heart rhythm.**

The AED is set up with an algorithm to analyze the electrocardiogram (ECG) and advise either shock or do not shock. The user is instructed in semi-automatic units to press another button on the AED to deliver a shock. The fully automatic AED will ask bystanders to “clear for shock” and begin a countdown to initiation of electrical discharge.

The AED will inform rescuers to resume CPR once a shock is delivered. It reanalyzes the rhythm after a predetermined amount of time to determine if additional shocks are necessary. AEDs typically deliver between 120 and 360 J of energy with each shock. The amount of electricity per shock depends on the number of previous shocks administered, the impedance of the chest wall, and whether a monophasic or biphasic waveform is used.³⁰ Leave the AED attached to the patient for further use. Patients may require further shocks, develop a rhythm not amenable to shock, or have a return of spontaneous circulation (ROSC).

PEDIATRIC CONSIDERATIONS

Ventricular fibrillation occurs in children (e.g., commotio cordis or congenital heart disease). The main issue with AED use in children is that the amount of electricity meant for the adult heart is delivered to the child’s heart. There are some AEDs available for use on an infant or pediatric patient.²⁰ These devices deliver lower energy per shock and use smaller pads (Figure 39-6). An adult AED can be used on a pediatric patient if pediatric pads are not available.³³ It is important that the electrodes do not touch when applied to the

FIGURE 39-6. An example of pediatric AED pads.

patient. It is more beneficial to use the adult settings than to continue CPR without defibrillation.³⁴

Many AEDs can accurately detect ventricular fibrillation in children of all ages and differentiate shockable from nonshockable rhythms with a high degree of sensitivity and specificity.^{20,33} Some AEDs are equipped with pediatric attenuator systems (e.g., pad-cable systems or a key) to reduce the delivered energy to a dose suitable for children. Use a pediatric dose-attenuator system for children 1 to 8 years of age. Use a standard AED if providing CPR to a child in cardiac arrest and an AED with a pediatric attenuator system is not available.³³

Use a manual defibrillator in children less than 1 year of age. Use an AED with pediatric attenuation if a manual defibrillator is not available. A standard AED may be used if neither is available. AEDs with relatively high-energy doses have been successfully used in infants with good neurologic outcomes, minimal skin injury, and minimal myocardial damage.^{33,35,36}

AED IN PREGNANCY

The AHA has a scientific statement on arrest in pregnancy^{19,37}: “The same currently recommended defibrillation protocol should be used in the pregnant patient as in the non-pregnant patient. There is no modification of the recommended application of electric shock during pregnancy.” Remember the need for left and upward compression of the uterus in late pregnancy to alleviate aortocaval compression if additional hands are available. Consider a perimortem cesarean delivery soon after arrest (Chapter 167).

ASSESSMENT

Reinitiate CPR after a shock is delivered. Assess for pulses and neurologic status after 2 minutes as per the advanced cardiac life support protocol. Provide supportive care in the supine or recovery position if the patient has regained consciousness and a pulse, with continuous monitoring of their condition until assistance arrives. The patient has converted into PEA if they return to sinus rhythm via the monitor without pulses. No further shock will be advised by the AED. Resume CPR.

AFTERCARE

Patients can occasionally deteriorate back into a shockable rhythm. Keep the patient connected to the AED until help arrives. Reevaluate the rhythm if the patient's condition changes or deteriorates. Transport the AED with the patient if they have ROSC. Many AEDs store the rhythm(s) detected, number of shocks delivered, and energy delivered, which can be useful after arrival at the Emergency Department.^{38,39}

COMPLICATIONS

AED rhythm analysis is automated, and there are very few complications.²¹ Device failures are rare.⁴⁰ They are categorized as device dependent or operator dependent.⁴¹ Improper storage and neglect of the AED can lead to a depleted battery. A large study reported almost 20% of AED failures were due to battery complications.⁴¹ The recognition sensitivity of AEDs to torsades de pointes and monomorphic ventricular tachycardia below a rate of 150 is poor.⁴² This would suggest missed opportunities for defibrillation in these cases. Nearly half of the reported device failures occurred during the attempt to deliver a recommended shock.⁴¹ A significant portion of those failures were due to unanticipated device shut down.⁴¹ The true incidence of these rare but disastrous events is difficult to calculate given the unknown number of uses. Many AEDs are associated with manufacturer defects and are recalled.^{4,40}

Most operator-dependent errors are due to set-up. Improper pad placement or connection of the pads to the AED is the most common. Pads must be connected to the AED and placed correctly to provide accurate rhythm analysis. Pads must not be touching or an electrical arc can be generated. Inability to correctly analyze the rhythm may result from improper connections of pads to patient or device, interference from rescuer electrical activity (i.e., contact with the patient), or movement of the patient during rhythm analysis.

Superficial burns and unintended or improper electrical delivery to patient or rescuer may result from the use of an AED. Care must be taken to avoid patient contact during defibrillation as this may result in the rescuer receiving a shock as well. Ensuring that the patient is not lying in a conductive medium (e.g., water) or near a flammable source (e.g., alcohol fumes, nitroglycerin patches) is important to avoid burns and fire that could be potentially generated.

Another common complication is thought to result from the electricity—termination of the ventricular fibrillation with subsequent development of PEA or other arrest rhythm not amenable to shock and without ROSC. Other complications associated with AED use are likely the result of cardiac arrest (e.g., myocardial stunning and pulmonary edema). An undiagnosed history of atrial fibrillation results in a theoretical risk for thromboembolism and stroke due to restoration of normal sinus rhythm and dislodging an atrial hematoma.

SUMMARY

AEDs placed in office buildings, in public access spaces, and with first responders decrease the time to rhythm analysis and defibrillation in those with a shockable rhythm. AEDs can be used in pediatric patients and other special populations. They have low complication rates. AEDs have been developed to allow laypersons to safely use them. They result in an improved survival rate from OOHCA. No difference in these outcomes has been found using monophasic AEDs versus biphasic AEDs. The determination regarding biphasic or monophasic depends on the ability to keep the unit charged, cost, and keeping the AED in working order. Always use the AED in conjunction with the activation of 911 (or local emergency care activation) and after the initiation of CPR.

Cardioversion and Defibrillation

Chirag N. Shah, Patrick J. Rogers, and Daniel S. Morrison

INTRODUCTION

The application of electricity to the heart induces depolarization of the myocardial cells in a uniform fashion. This may interrupt reentry circuits that are inducing an arrhythmia. Depolarization of the myocardium allows the sinus node to resume its normal pacing function. This is accomplished with the transthoracic application of a direct-current electrical shock.

A large amount of literature exists on the application of electricity for medical applications and dates back to the 17th century. Peter Abildgaard shocked hens in 1775. He found the application of electricity to the body and head renders the animal lifeless and electrical shocks to the chest revived the heart. Claude S. Beck made the first defibrillator that used AC current from a wall socket (**Figure 40-1**). It was devised for exposed hearts and used in the Operating Room. Naum L. Gurvich developed the world's first commercially available transthoracic DC defibrillator in the USSR in 1952 (**Figure 40-2**).

The techniques of cardioversion and defibrillation are relatively straightforward and practically identical. The main differences are the indications and use of synchronization with cardioversion. **The purpose of cardioversion is to deliver a precisely timed electrical current to the heart to convert an organized rhythm to a more hemodynamically stable rhythm. The purpose of defibrillation is to deliver a randomly timed high-energy electrical current to the heart to restore a normal sinus rhythm.** These techniques are currently performed by emergency medical technicians, nurses, paramedics, physicians, and a variety of other health care workers on a daily basis. This chapter discusses the techniques of manual cardioversion and defibrillation. A discussion of advanced cardiac life support (ACLS), cardiac rhythms, chemical cardioversion (Chapter 38),

FIGURE 40-1. Beck's defibrillator. (Photo used with permission of Dittrick Medical History Center.)

automatic external defibrillation (Chapter 39), and Pediatric Advanced Life Support is beyond the scope of this chapter.

INDICATIONS

CARDIOVERSION

Electrical cardioversion is performed either electively or emergently. The Emergency Department role of electrical cardioversion is usually limited to urgent or emergent situations or when medical therapy has failed.^{1,2} This includes symptomatic reentry tachycardias (i.e., supraventricular tachycardia, atrial fibrillation, atrial flutter, and Wolf-Parkinson-White syndrome) and hemodynamically stable ventricular tachycardia associated with acute myocardial infarctions, altered levels of consciousness, chest pain, congestive heart failure, dizziness, dyspnea, hypotension, presyncope, pulmonary edema, shock, or syncope.

FIGURE 40-2. Gurvich's defibrillator. (Photo used with permission from Dittrick Medical History Center.)

Electrical cardioversion is often preferred in the Emergency Department to chemical cardioversion for many reasons. Electrical cardioversion is simple and quick to perform. It is immediately effective in most cases. It may be more successful than chemical cardioversion. The complications are usually minimal. Potential allergic reactions and toxic effects are nonexistent with electrical cardioversion.

DEFIBRILLATION

Defibrillation is indicated when ventricular fibrillation or ventricular tachycardia has not spontaneously converted to an organized rhythm. Ventricular fibrillation and ventricular tachycardia are rarely spontaneously reversible and are not compatible with life. Defibrillation must be performed immediately if the patient is found pulseless, unconscious, apneic, or during the Advanced Cardiac Life Support (ACLS) protocol. "Fine" ventricular fibrillation can be present and may be confused with asystole. It may be secondary to low gain amplitude or improper lead positioning. Rotate the "quick-look" paddles 90° and recheck the monitor. Select a different lead on the monitor and/or increase the gain to determine if the cardiac rhythm is fine ventricular fibrillation or asystole. Ventricular fibrillation or ventricular tachycardia secondary to myocardial ischemia or infarct, electrolyte abnormalities, long QT syndromes, hypothermia, or drug toxicity (e.g., digoxin, tricyclic antidepressants, antiarrhythmics, antihistamine, and macrolide antibiotic combinations) may convert to a more hemodynamically stable rhythm with defibrillation.

CONTRAINDICATIONS

CARDIOVERSION

Cardioversion is contraindicated for several cardiac rhythms or conditions. Do not cardiovert a patient with a rhythm of ectopic atrial tachycardia, junctional tachycardia, multifocal atrial tachycardia, sick sinus syndrome, or sinus tachycardia. Cardioversion is not effective for these rhythms and may result in a worse (i.e., ventricular fibrillation or ventricular tachycardia) postshock rhythm. **Cardioversion of atrial fibrillation should not be attempted unless it is known with certainty that the current episode commenced within the last 48 hours.** Cardioversion of chronic atrial fibrillation, or atrial fibrillation having lasted longer than 48 hours, may dislodge atrial thrombi and result in thrombus embolization and end-organ injury (e.g., stroke). There is some controversy in the literature regarding the cardioversion of atrial flutter greater than 48 hours old without anticoagulation.^{3,4} Elective cardioversion of atrial flutter should not be performed if the rhythm has lasted for longer than 48 hours. Atrial fibrillation and flutter can coexist. **Do not cardiovert a patient with a known thrombus in the atria, atrial appendage, or ventricle without first consulting a Cardiologist.** Cardioversion in patients with digoxin toxicity should be avoided. Cardioversion in digoxin toxicity is usually ineffective and has been associated with postshock ventricular tachycardia and ventricular fibrillation.⁵ Cardioversion is contraindicated when the patient is without a pulse or has an underlying cardiac rhythm of asystole.

Alterations in the chemical or metabolic milieu of the myocardium may cause subsidiary pacemakers to become more dominant and overtake the sinus mode. This is referred to as enhanced automaticity and can be due to drugs (e.g., digoxin), hypoxia, or electrolyte abnormalities (e.g., hypokalemia or hypomagnesemia). Uniform depolarization with electricity does not terminate this abnormality, as uniform depolarization already exists. The rhythms

that may occur are sinus tachycardia, ectopic atrial tachycardia, multifocal atrial tachycardia, and the digoxin toxic rhythms. Treatment of the underlying etiology is the treatment of choice.

DEFIBRILLATION

There are few contraindications to defibrillation. The main contraindication is in a patient who has made it clear that he or she does not wish to be resuscitated. Defibrillation should not be used for arrhythmias other than ventricular tachycardia or ventricular fibrillation.

EQUIPMENT

- Cardioverter-defibrillator unit
- Conductive jelly or pads
- Suction source, tubing, and catheter
- Airway management supplies
- Advanced Cardiac Life Support (ACLS) medications
- Intravenous sedative agents
- Cardiac monitor
- Noninvasive blood pressure monitor
- Pulse oximeter
- Oxygen source and tubing
- Nasal cannula or face mask to deliver oxygen

THE CARIOVERTER-DEFIBRILLATOR UNIT

The typical cardioverter-defibrillator unit performs cardioversion, defibrillation, and pacing (Figures 40-3, 40-4, and 40-5). A list of available features on a typical unit is listed in Table 40-1. Newer models feature lower power outputs to accommodate their use in children, pediatric and adult paddles, biphasic waveforms, and cardiac pacing capabilities. Each Emergency Physician should be familiar with the specific unit at their facility. The general features of the unit are discussed below.

The unit is self-contained. It plugs into a standard electrical outlet. The unit contains rechargeable batteries, which allows it to be portable. An oscilloscope provides real-time monitoring of the patient's cardiac rhythm. A continuous electrocardiographic (ECG) rhythm strip providing documentation on paper is standard with

FIGURE 40-4. An example of a cardioverter-defibrillator with paddles.

each unit. It produces a hard copy for the medical record. Numerous dials or electronic touchpads with digital displays allow the operator to set the working mode, energy level, pacemaker settings, and oscilloscope input (i.e., ECG leads or “quick-look” paddles). The depolarizer within the machine provides direct electric current for cardioversion and defibrillation.

The synchronizer permits the discharge of electric current based on the patient's ECG waveform. It searches for the R and S waves of the ECG tracing to determine the proper time to discharge the current. It avoids delivering the current during the repolarization phase of the myocardial action potential, when the heart may convert to ventricular fibrillation or ventricular tachycardia. A brief delay is noted while the synchronizer searches for an appropriate time to discharge the current when the operator pushes the button to discharge the unit.

MONOPHASIC VERSUS BIPHASIC UNITS

All cardioverter-defibrillator units in the past generated monophasic waveform current to deliver the shock. Biphasic waveform current generating units were developed in the late 1990s. **The biphasic units deliver more current at a lower energy level to cardiovert or**

FIGURE 40-3. Two examples of cardioverter-defibrillator units.

FIGURE 40-5. An example of a cardioverter-defibrillator with patches.

TABLE 40-1 Characteristics of a Typical Cardioverter-Defibrillator Unit

Adult and pediatric paddles
Cardioversion capability
Continuous ECG rhythm-strip documentation on paper
Defibrillator capability
Depolarizer
On/off switch
Oscilloscope to monitor cardiac rhythms
Pacing capabilities
Portability
“Quick-look” paddles or pads
Safety mechanism to prevent accidental electrical discharge
Standard ECG leads (three) to attach to the shoulders and lower extremity
Synchronizer
Wide range of energy selection

defibrillate (Tables 40-2 and 40-3). Biphasic units are more effective in cardioverting and defibrillating patients. Biphasic units are significantly more expensive than monophasic units. Determine which type of unit is available at your facility to determine the proper energy levels to administer.

TYPES OF ELECTRODES

The electrodes are referred to as either paddles (**Figure 40-4**) or patches (**Figure 40-5**) depending on their configuration. They must be firmly applied to the patient's torso. They allow a “quick look” and transmit the patient's cardiac rhythm to the oscilloscope and let the Emergency Physician make decisions. Each paddle has a button on which a thumb is to be placed (**Figure 40-4**). This serves as a safety mechanism. Both buttons must be depressed simultaneously to discharge the current. This prevents accidental and premature discharge of current, which may cause injury to the patient, the operator, or bystanders. Most newer units use self-adhesive, single patient use, disposable patches as an alternative to paddles (**Figure 40-5**). The patches apply to the torso similar to ECG leads. They connect by cables to the cardioverter-defibrillator unit.

Paddles or patches come in various shapes and sizes. Adult paddles or patches are round, oval, or rectangular in shape. They measure 8 to 10 cm in greatest diameter. They can be used on children weighing more than 10 kg or over 1 year of age, adolescents, and adults. Pediatric paddles or patches also come in a variety of shapes and measure 4 to 6 cm in greatest diameter. The pediatric paddles are to be used in children weighing less than 10 kg or less than 1 year of age.⁶ Some units contain both adult and pediatric paddles or the

TABLE 40-3 Recommended Initial and Subsequent Biphasic Energy Levels for Cardioversion or Defibrillation

Situation	Initial energy setting	Subsequent energy settings*
Adults		
Defibrillation	120 J	150, 200, 200 J
Synchronized cardioversion	70 J [†] 75 J [‡]	120, 150, 150 J
Children

[†]E Series.

[‡]M Series, CCT, R Series.

ability to use both adult and pediatric patches. The adult electrode slides off the paddle handle to reveal the pediatric-size electrode.

The cutoff of 10 kg and 1 year of age is relative in choosing the proper paddle or patch for a small child. **Choose the largest paddle or patch that will achieve complete and full contact with the child's chest wall.** Larger paddles and patches will allow a greater amount of myocardium to be depolarized while decreasing the current density applied and minimize myocardial injury. **The paddles or patches must be at least 2 to 3 cm apart to prevent electrical bridging and burn injury to the child. Using paddles or patches that are too large will deliver the electric current over too great an area and decrease its effectiveness.** The opposite is true in adults. Using paddles or patches that are too small will deliver the electric current over a small area, making it too intense, and increases the potential damage to the myocardium.

ELECTRODE POSITIONING

The paddles or patches may be positioned in several different patterns.⁷⁻⁹ The most commonly used positions are anterolateral for paddles (**Figure 40-6**) and either anterolateral or anteroposterior (**Figure 40-7**) for patches. Anterolateral paddles or patches are positioned with the anterior paddle at the right upper sternal border over the second and third intercostal spaces. The lateral paddle or patch is placed in the left midaxillary line centered over the fourth and fifth intercostal spaces. Anteroposterior placement is often used

**FIGURE 40-6.** Anterolateral pad and paddle positioning.**TABLE 40-2** Recommended Initial and Subsequent Monophasic Energy Levels for Cardioversion or Defibrillation

Cardiac rhythm	Initial energy setting	Subsequent energy settings*
Adults		
Atrial fibrillation	100 J	200, 300, 360 J
Atrial flutter	50 J	100, 200, 300, 360 J
Supraventricular tachycardia	50 J	100, 200, 300, 360 J
Ventricular tachycardia	200 J	300, 360 J
Ventricular fibrillation	200 J	300, 360 J
Children		
Supraventricular tachycardia	0.5 J/kg	1.0 J/kg
Ventricular tachycardia	2.0 J/kg	4.0 J/kg
Ventricular fibrillation	2.0 J/kg	4.0 J/kg

FIGURE 40-7. Anteroposterior pad and paddle positioning.

with disposable patches rather than paddles (**Figure 40-7**). The anterior patch is centered over the sternum, and the posterior patch is placed between the scapulae. A randomized prospective trial evaluated the anteroposterior versus anterolateral patch position in converting atrial fibrillation.⁹ The anteroposterior patch position was more effective in converting the rhythm. Another study showed no difference in the patch position.¹⁰ A third study of atrial fibrillation showed the anterolateral position worked best.¹¹ Adult patches or paddles can be substituted if pediatric patches or paddles are required but not available.⁷ Roll the child onto their right side and place the patches in the anteroposterior position. Other positions include the latero-lateral (i.e., axilla-to-axilla) position and the parasternal-infraclavicular (i.e., oblique, left anterior chest to right posterior infrascapular) position.⁸

CONDUCTIVE CONTACT MEDIUM

Electrically conductive contact medium should always be applied between the electrode and the patient's chest wall. Conductive gel pads are commercially available and primarily used. The contact material helps to maximize current flow, minimize resistance, reduce transthoracic impedance, and prevent thermal or electrical burns to the chest wall. The self-adhesive disposable patches are prelubricated with contact medium and need no additional contact medium.

Contact medium is required with the older units that use paddles. Self-adhesive, disposable conductive gel pads can be used. An alternative is the gel or paste form of contact medium. The contact medium should be applied to the paddles generously. **It should not connect the paddles because it would divert the electric current along the chest wall, away from the heart, and cause burns to the chest wall.** Saline-soaked gauze squares can be used in an emergency if contact medium is not available. The saline must be squeezed out of the gauze squares to prevent the accumulation of liquid on the chest wall and bridge the two paddles.

PATIENT PREPARATION

Place the patient supine on a bed. Attach the cardiac monitor, noninvasive blood pressure monitor, pulse oximetry, and oxygen to the patient. Obtain intravenous access. **Suction and resuscitation equipment should be readily available in case it is needed.** Cardioversion is scary and extremely uncomfortable for patients. Explain the risks, benefits, and alternative procedures to the patient and/or their representative if cardioverting. Obtain an informed consent for the procedure and place this in the medical record. Premedicate the patient prior to cardioversion if no contraindications exist, the patient is hemodynamically stable, and they can tolerate a delay to cardioversion.¹² The choice of the appropriate sedative agent (Chapters 12 and 159) is physician-dependent. Commonly used agents include etomidate, ketamine, midazolam, methohexital, propofol, and thiopental. Diazepam and lorazepam are not often used because of the long delay to onset of their action.

TECHNIQUES

Stand at the patient's left side. Turn on the cardioverter-defibrillator unit. Set the display to "quick-look." Instruct the nurses to apply the ECG leads to the patient. Grasp the left paddle labeled *sternum* with the left hand and the right paddle labeled *apex* with the right hand (**Figure 40-4**). This is the anterolateral paddle position. Apply the paddles and observe the patient's cardiac rhythm. Set the mode as asynchronous (i.e., defibrillation) or synchronous (i.e., cardioversion) based on the patient's cardiac rhythm. Set the energy level (**Tables 40-2 and 40-3**). **Older defibrillator units deliver monophasic waveform energy. Newer units deliver biphasic energy, which is more effective and delivers more current at lower energy settings.**

Apply conductive pads to the patient's torso in the anterolateral position. Alternatively, apply conductive jelly to the paddles liberally and rub them together to coat the electrode surface completely. Apply the paddles firmly to the torso in the anterolateral position. **The paddles should be separated from each other by at least 2 to 3 cm to prevent arcing of the current and injury to the patient.**

Prepare to deliver the electric current to the patient. Charge the paddles. This must be done on the unit or the paddles before the initial and each subsequent discharge. It takes approximately 2 to 5 seconds to charge the paddles following activation of the charge button. Cardiopulmonary resuscitation (CPR) can be performed while the unit is charging. **Ensure that nurses and other assistants are not touching the patient or the stretcher by saying "clear."** The assistant ventilating through a bag-valve device attached to an endotracheal tube does not need to drop the bag, as plastic is nonconductive. Consider turning off the oxygen during shock delivery. **The person who will deliver the charge to the patient should ensure that their body is not in direct contact with the patient or the stretcher.**

The American Heart Association (AHA) recommends limiting the disruptions to CPR yet also recommends stopping CPR during defibrillation.^{13,14} This has led to interest in hands-on defibrillation. It has been shown in limited studies to be safe and effective, and it does not require the cessation of CPR.^{15,16} The best advice for now is to use hands-off defibrillation until more information on the safety of this procedure is obtained.

Reevaluate the patient's cardiac rhythm. Deliver the charge by simultaneously pressing the discharge buttons on each paddle. Observe the monitor and reevaluate the patient's cardiac rhythm. The unit can be recharged to deliver another electric charge to the patient if indicated.

The technique using self-adhesive disposable patches on newer units is similar with a few exceptions. Apply the patches in the anteroposterior position (**Figure 40-7**). No supplemental contact medium is required. Select the desired energy level (**Tables 40-2 and 40-3**). Charge the cardioverter-defibrillator unit by pressing the charge button on the unit. Press the discharge button on the cardioverter-defibrillator unit to deliver the charge to the patient. Reevaluate the need for further therapy.

The cardioverter-defibrillator unit may not deliver a shock. Check that the unit is plugged in, that no touching or bridging of the pads or gel has occurred on the patient's chest, and that the paddles are charged. The cardioverter-defibrillator unit may not be able to properly sense the R wave in synchronization mode with a rapid supraventricular rhythm. Reattempt to deliver the shock by holding down the discharge button for 15 seconds. This will give the cardioverter-defibrillator unit more time to determine and find a proper time to deliver the shock. **Switching to asynchronous mode will allow the delivery of the shock, but risks shocking at the inappropriate time and converting the rhythm to ventricular tachycardia or ventricular fibrillation.** Consider intravenous medication to slow the heart rate or chemically convert the rhythm rather than applying an asynchronous shock.

ALTERNATIVE TECHNIQUE

The use of double defibrillation has caught the attention of researchers. It uses two machines with their own patches (**Table 40-4**) and the sequential defibrillation of the patient.¹⁷⁻²⁶ The patient receives between 400 and 600 J, depending on the setting of each defibrillator. It has been used by Electrophysiologists in the catheterization laboratory and for refractory ventricular fibrillation. The defibrillation may work because of the higher energy applied across the myocardium, the different defibrillation vectors, or another not yet discovered mechanism. The results are mixed in terms of survival to hospital discharge. More research is being done to answer these questions. For the time being, it does not hurt to try if standard defibrillation does not work.

AFTERCARE

No specific aftercare is required related to the procedure of cardioversion or defibrillation. If using a cardioverter-defibrillator unit with paddles and conductive gel or paste, it is possible to cause a thermal burn to the skin. This should be treated as any other skin burn. Continuously monitor the patient after they are cardioverted or defibrillated. Almost all patients receiving cardioversion or defibrillation will be admitted to the hospital. A successfully cardioverted patient may occasionally be discharged home. The decision to discharge the patient should be made in consultation with the patients Primary Care Physician and/or a Cardiologist.

COMPLICATIONS

Complications of cardioversion can range from none to death. Thermal and electrical burns are potential injuries. Skin burns may result, the severity of which increases depending on the energy level used and the number of shocks delivered. Care must be taken to avoid contact between the ECG monitor leads and the paddles or contact of the paddles with each other, as sparks or fire may result. Burns can be minimized by using electrically conductive contact media and firmly applying the paddles to the patient. Remove any fluid materials on the chest wall (e.g., conductive jelly, saline, sweat, urine, or water) as they can form a bridge between the paddles or pads and result in arcing and thermal burns to the thorax. Remove any nitroglycerin patches or ointments from the patient's torso. Ensure that there are no open oxygen sources that could ignite when the unit is discharged. Repeated shocks will produce only a mild erythema to the chest wall if performed correctly. Systemic emboli may occur from clots in the left atrium becoming dislodged if the underlying rhythm prior to the cardioversion or defibrillation is atrial fibrillation.

Occasionally, hypertension, other arrhythmias, or heart block may develop. Ventricular fibrillation may result from a synchronized or nonsynchronized shock delivered on the T wave.²⁷⁻²⁹ This usually occurs immediately and can be corrected with a nonsynchronized countershock. **Ensure that the unit is in synchronous mode, not asynchronous mode, when cardioverting an organized cardiac rhythm.** Always observe the monitor before delivering a countershock to ensure that it is required. Change the monitor

lead so that the T wave is smaller than the R wave and the unit will not cardiovert during a vulnerable period if the T wave is large. Ventricular fibrillation that occurs within 30 to 60 seconds after the delivery of a synchronous shock is often due to digoxin toxicity and is difficult or impossible to correct. Transient ST-segment elevation may occur.³⁰

Creatine kinase enzyme elevations may occur, with most being skeletal muscle in origin.²⁸ Cardiac enzymes can become elevated. The higher the energy level used and the more countershocks given, the greater is the muscle damage. Usually no significant permanent myocardial damage occurs.

Do not apply the paddles or patches directly over an implanted defibrillator or pacemaker. The electric discharge can permanently damage these devices. Adjust the paddle or patch position so they are not directly over these devices.

Avoid injury to yourself or others by ensuring that no one is in contact with the bed or the patient when the shock is administered. Such injuries can range from mild shocks and burns to cardiac dysrhythmias. An improperly functioning unit can cause injury despite being used properly. Periodic maintenance and calibration of the unit are necessary.

SUMMARY

Cardioversion and defibrillation are the processes of applying electric current to a patient's chest to terminate a dysrhythmia. Cardioversion is a safe and effective method of converting reentry arrhythmias. A trial of medical therapy is warranted if the patient is stable. Cardioversion should be initiated as soon as possible if the patient is unstable. Consider administering parenteral sedation as cardioversion is anxiety provoking and painful for the patient. Cardioversion should be performed in the synchronized mode. Always be prepared for ventricular fibrillation or ventricular tachycardia as a result of cardioversion of an organized rhythm. ACLS medications and airway support must be readily available. Defibrillation is essentially cardioversion of unstable ventricular tachycardia or ventricular fibrillation. It is performed like cardioversion except that synchronization and sedation are not required.

Transcutaneous Cardiac Pacing

Chirag N. Shah, Patrick J. Rogers, and Daniel S. Morrison

INTRODUCTION

Transcutaneous cardiac pacing (TCP) was first documented as a technique in 1872.¹ It was successfully demonstrated in two patients with underlying cardiac disease and symptomatic bradycardia.¹ The clinical difficulty of open-chest pacing, transvenous pacing, and open-chest cardiac massage for the treatment of "ventricular

standstill" in an emergent setting has been recognized.^{1,2} Animal experiments were performed using electrodes placed in various positions prior to the use of subcutaneous needle electrodes at points "in a line transversing the ventricles."¹ The use of the procedure during eight surgical cases in which cardiac arrest occurred resulted in five patients successfully surviving to discharge.² Cardiac monitoring during surgery was not routinely performed and the underlying rhythm being paced was not specifically determined in all reported cases.

Further work related to TCP seems to have lapsed until the 1980s. Several groups studied the technique for treatment of symptomatic bradycardias, asystolic cardiac arrest, and bradysystolic cardiac arrest in the hospital and in the Emergency Department.³ They concluded that TCP is as successful as transvenous cardiac pacing in obtaining electrical and mechanical capture in bradysystolic arrests. TCP was easier to initiate than transvenous cardiac pacing. However, TCP did not improve the overall survival rates for these patients.³

TCP was recommended for cardiac emergencies by the International Liaison Committee on Resuscitation (ILCOR) guidelines beginning in 1980 and is currently recommended for treatment of symptomatic bradycardias, especially when the conduction block is at or below the His-Purkinje level.⁴ TCP is no longer indicated for the treatment of asystolic cardiac arrest since there are no improvements in rate of hospital admission or survival to hospital discharge.⁵

With current technology and equipment, TCP offers several advantages when compared to the placement of a transthoracic cardiac pacemaker (Chapter 42) or transvenous cardiac pacemaker (Chapter 43) in the Emergency Department. The procedure requires minimal training and can be performed quickly. TCP is a noninvasive procedure and is not associated with the major complications of placing more invasive pacemakers. This includes inadvertent arterial puncture, hemorrhage, pneumothorax, or cardiac tamponade from cardiac rupture. **TCP is an ideal early and temporary intervention for patients requiring stabilizing cardiac pacing support until more invasive procedures can be arranged in the proper clinical setting.**

ANATOMY AND PHYSIOLOGY

Electrical impulses originating in the sinoatrial (SA) node create an action potential that is conducted along the intrinsic cardiac nerve pathways to the atrioventricular (AV) node and disseminated through the His-Purkinje system. This action potential stimulates electrolyte flux, myocardial muscle depolarization, and subsequent cardiac muscle contraction. Electrical propagation and myocardial contraction occur separately in the atria and ventricles. The atria contract slightly ahead of the ventricles during ventricular diastole. This timing delay assists in filling the ventricles prior to their next ventricular systolic phase. The intrinsic heart rate is controlled by a balance of input from the sympathetic nervous system acting directly on the cardiac muscle and the parasympathetic nervous system acting most prominently at the SA and AV nodes.

The intrinsic heart rate can be disrupted by a wide variety of disease processes. The blood supply for the SA node is from an early branch of the right coronary artery. Coronary artery disease can disrupt blood flow and oxygen supply to the myocardium and create areas of cardiac ischemia that affect the conduction system, the impulse production, or conduction at the SA and AV nodes. Cardiac ischemia can result in action potential conduction delays and heart blocks, with resultant bradycardia and hypotension. Electrolyte disturbances (e.g., hyperkalemia), structural heart disease, drug toxicity (e.g., calcium channel blockers and beta-blockers), systemic

toxins (e.g., cyanide), and systemic hypothermia are other causes of intrinsic conduction delays and heart blocks.

TCP delivers an extrinsic electrical impulse that overrides the intrinsic cardiac action potential. Initial pulse durations used were short at 1 to 2 milliseconds. They have now been extended to 20 to 40 milliseconds to decrease the threshold current (i.e., the current needed for cardiac muscle stimulation). The longer pulse duration decreases patient comfort as the degree of skeletal muscle contraction is generated by the TCP pulse.⁶ Most TCP devices can generate up to 200 milliamps (mA) of current. The mean pacing current needed to obtain capture ranges from 40 to 100 mA.⁶⁻⁹

INDICATIONS

TCP is technically the fastest and easiest method of emergency cardiac pacing. It is a temporary intervention prior to implementation of transvenous cardiac pacing, placement of a permanent cardiac pacemaker for primary cardiac dysfunction, or until the underlying etiology of the bradycardia can be reversed (e.g., myocarditis).¹⁰⁻¹⁵ It is indicated for patients with symptomatic bradycardia from any etiology in whom pharmacologic interventions (e.g., atropine) have been unsuccessful.¹⁶ It can be effectively applied in the prehospital setting by Emergency Medical Services (EMS) personnel, in a clinic, in the Emergency Department, or in the hospital. **TCP is quick, simple, and not associated with the morbidity or mortality of transvenous cardiac pacing in patients with bradyarrhythmias expected to be transient (e.g., digoxin toxicity) or AV block in the setting of inferior wall myocardial infarction.**

It is indicated in patients with AV conduction blocks and sinus node dysfunction.¹⁷ It should be performed in symptomatic patients (e.g., syncope, presyncope, dizziness, fatigue) with complete or third-degree AV block, asystolic pauses exceeding 3 seconds, or an escape pacemaker rate less than 40 beats per minute.¹⁸ Patients with type I or type II second-degree AV block who are symptomatic should be transcutaneously paced. Symptomatic bifascicular block is an indication for temporary TCP. Patients with sinus node dysfunction are candidates for pacing. Sinus node dysfunction includes sinus pause with symptoms of cerebral hypoperfusion (e.g., syncope, presyncope, dizziness), chronic sinus node dysfunction with or without symptoms but with escape rates of less than 40 beats per minute, or symptomatic sinus bradycardia.

TCP electrodes should be placed on patients in anticipation of potential clinical deterioration and bradyarrhythmias in the appropriate setting.⁸ For example, a patient with a beta-blocker overdose may present with a slow or normal heart rate but otherwise be asymptomatic. Hemodynamic deterioration is possible. Preparation for TCP (i.e., electrodes applied and connected to generator unit, unit in standby mode, etc.) can be easily accomplished while further efforts related to the diagnosis and treatment are undertaken. The transcutaneous pacer can be immediately activated without the delays associated with obtaining the equipment and setting up the system if the patient develops a bradyarrhythmia.

TCP can be used for overdrive cardiac pacing in event of a supraventricular or ventricular tachydysrhythmia (e.g., ventricular tachycardia, torsade de pointes, or paroxysmal supraventricular tachycardia) in the patient who is clinically stable.¹⁹⁻²⁴ A major limitation to overdrive cardiac pacing would be the maximum rate that the pulse generating unit can achieve. The technique requires pacing the patient at a rate of 20 to 60 beats per minute faster than the tachydysrhythmia.²³ Patients do not usually tolerate transcutaneous overdrive pacing due to the accompanying chest wall contractions and discomfort. The transvenous or transthoracic route is preferred for overdrive pacing of the myocardium.

CONTRAINDICATIONS

There are no absolute contraindications to TCP.^{14,15} Hypothermia has been considered a relative contraindication to TCP. The associated bradycardia seen during hypothermia is thought to be a result of direct myocardial depression and decreased metabolic rate.^{25,26} Concerns related to ventricular irritability, dysrhythmias, and resistance to defibrillation have led to the idea that electrical manipulation of the hypothermic myocardium should be avoided.²⁷ There are case reports of successful TCP use during rewarming for severe hypothermia.²⁸ TCP is relatively contraindicated for prolonged bradysystolic cardiac arrest due to the overall poor resuscitation rates and outcomes of these patients.^{8,29,30} TCP is no longer indicated for the treatment of asystolic cardiac arrest since there are no improvements in the rates of hospital admission or survival to hospital discharge in this setting.⁸

EQUIPMENT

- Pulse generator and monitor unit
- Pacing cable attached to the monitor
- Pacemaker patches or electrodes
 - 6×7 cm for infants and young children
 - 13×15 cm for older children and adult
- Electrocardiogram (ECG) patches or electrodes (if the pacemaker patches and unit do not monitor the patient)
- ECG cable attached to cardiac monitor (if the pacemaker patches and unit do not monitor the patient)
- Intravenous access supplies
- Sedative and analgesic medications
- Povidone iodine or chlorhexidine solution
- Skin razor

Most commercially available cardiac defibrillators used in the Emergency Department are a combination cardioverter, defibrillator, and cardiac pacer with an associated ECG monitor (**Figure 41-1**). The unit is usually available on all code carts in the Emergency Department and throughout the hospital. The Emergency Physician should become familiar with their specific institutional equipment prior to an emergent situation requiring its use.

The pacing patches are either round or rectangular and come packaged as pairs with illustrations to demonstrate proper placement

FIGURE 41-1. The cardiac monitor/defibrillator with TCP capabilities and attached surface patches.

FIGURE 41-2. TCP electrodes with diagrams demonstrating placement of the electrode.

of the electrode (**Figure 41-2**). The negative electrode will be labeled “front” or “apex.” The positive electrode may be labeled “back” or “posterior.” Most modern TCP electrodes are disposable, single patient use, and multipurpose. The one electrode can be used to perform cardioversion, defibrillation, ECG monitoring, and TCP. Some older units may not have this flexibility and require separate ECG leads.

PATIENT PREPARATION

If time allows, discuss the procedure with the patient and/or their representative. This should include the reason for performing the procedure, the risks of the procedure including pain-related issues and how pain will be addressed, and the benefits of the procedure including expected symptom improvement. There is a small risk of developing a ventricular tachydysrhythmia during TCP.³¹ A written and signed consent documenting this conversation is always preferred. However, it is not required in an emergent situation. Documentation of the conversation in the medical record should be adequate in an emergent situation. Preparation for transvenous cardiac pacing (Chapter 43) can be simultaneously undertaken if TCP is unsuccessful.

The patient's skin should be relatively clean and free of debris. Warm, soapy water can be used as a cleansing agent. Avoid potentially flammable cleansing solvents (e.g., alcohol-based solutions). Dry the skin. Trim the back and chest hair if the patient is hirsute and the pacing patches are poorly adherent. Trimming is preferred to shaving to avoid skin disruption or abrasions that may cause increased pain, skin irritation, and bacteremia during the procedure. If shaving is required and pacing is not emergently required,

apply povidone iodine or chlorhexidine to the area and allow it to dry. This will decontaminate the skin prior to shaving.

Administer sedative and analgesic medications (Chapter 159) to manage the discomfort related to the chest wall skeletal muscle contractions associated with TCP.³¹ Pain levels associated with TCP were found to be moderate to moderately severe (mean of 3.2 on a 5-point scale) in 30 healthy volunteers.⁹

TECHNIQUE

ELECTRODE PAD PLACEMENT

Two pacing electrodes must be applied to the thorax (**Figure 41-2**). Place the front, anterior, or negative labeled electrode on the anterior chest wall, and centered over the apex of the heart (**Figure 41-3A**) or over the V₃ lead position (**Figure 41-3B**). The anterior electrode should be positioned in females by lifting the breast and placing it under the fold of the breast and against the chest wall. Place the back, posterior, or positive labeled electrode directly behind the anterior electrode and to the left of the thoracic spine, between the spine and the scapula (**Figure 41-3C**). Avoid trapping air or debris under the pad during placement. The positive electrode may be alternatively placed on the right upper chest and the negative electrode over the apex of the heart (**Figure 41-4**).

TCP

Connect the cable from the electrodes to the pacer/monitor unit. Turn the output current (mA) dial as low as possible (**Figure 41-5**). Set the pacing rate between 80 and 90 beats per minute. Select the pacer function of the pacer/monitor unit. Turn the unit on. Gradually increase the current output by 5 to 10 mA at a time until capture is achieved (**Figure 41-6**). **Note the mA output value that is required to initiate TCP. This is known as the threshold current.** Increase the output current approximately 10%, or 5 to 10 mA, above threshold current. Maintain the output current at this level.

Start with the output current set at maximum in the near-arrest or unconscious patient. Turn the unit on. Dial the output current down until capture is lost. This is the threshold current. Raise the output to restore capture. Increase the output current approximately 10%, or 5 to 10 mA, above threshold current. Maintain the output current at this level.

Some pacer/monitor units can operate in a “standby mode.” This mode can be used for patients who are at risk of developing symptomatic bradycardia but are currently clinically stable. Set the unit to “pacing mode.” Attach the pacer electrodes to the patient and the unit. Initiate a brief period of TCP at a rate slightly faster than the patient's intrinsic rate to determine the threshold current and if

FIGURE 41-3. Placement of TCP electrodes. **A.** Anterior (negative) electrode placed over the cardiac apex. **B.** Anterior (negative) electrode position centered over the V₃ lead position. **C.** Posterior (positive) electrode position.

FIGURE 41-4. Alternative TCP electrode positions. The negative electrode is positioned over the cardiac apex. The positive electrode is positioned on the right anterior chest wall.

capture is possible. Turn the unit off. Set a reduced rate on the pacer dial. This rate should be below the patient's current heart rate but also be the minimal heart rate acceptable to the Emergency Physician for the patient. Switch the unit to "standby mode" and turn it on. The pacer function will automatically engage if the patient's heart rate falls below the value set on the unit.

OVERDRIVE PACING

Full cardiac resuscitation equipment should be available and ready at the bedside as rhythm acceleration and subsequent hemodynamic instability are possible.²⁰ The pacer electrodes and pacing unit set-up remain the same to perform overdrive TCP for a tachydysrhythmia. Administer sedative and analgesic medications as required. Set the current output at 120 mA, as this current generally will exceed the threshold value for most patients. Turn on the unit and initiate asynchronous cardiac pacing at a rate of 20 to

60 beats per minute higher than the intrinsic rate of the tachydysrhythmia.^{20,23} Once capture is achieved, decrease the current output to just above the threshold current. Slowly lower the pacing rate to decrease the patient's heart rate to the desired level. TCP for overdrive pacing may not be possible due to the upper heart rate limit of the available pacing unit.

PACING PEDIATRIC PATIENTS

There are limited data available on the use of TCP in the pediatric population. The indications for the procedure are the same as those in adults. The technique used to accomplish TCP is the same as in an adult. TCP is often more effective in children because their smaller chest wall results in a lower transthoracic resistance to the pacing current.

There are special considerations when performing TCP in the pediatric population. TCP has been undertaken in newborns with complete AV node block.³² This small case series of two patients, as well as others, documented significant thermal injury to the underlying skin.^{32,33} This was most likely related to the newborn's thin and fragile skin. Increased monitoring of the skin surrounding the electrodes is mandatory in children, especially in cases of prolonged TCP. Pediatric-sized transcutaneous pacing electrodes are available and should be used to limit surface contact. A study comparing the use of adult versus two specially sized pediatric electrodes for TCP demonstrated a lower mean current output with the smaller pads (63 mA versus 51 to 53 mA).³⁴ Appropriately sized electrodes are available for children under 15 kg (33 pounds) and should be used.

Only one study has documented the outcomes of TCP in pediatric out-of-hospital cardiac arrest.³⁵ In six drowning victims and three sudden infant death syndrome patients who received TCP by EMS providers, only two patients achieved electrical and mechanical capture. Both patients had an initial rhythm of asystole. In total, seven patients presented with asystole and two patients presented with ventricular fibrillation. Only one patient with an initial rhythm of asystole survived to hospital discharge but was severely neurologically impaired and died 6 months later. Current guidelines do not recommend TCP for asystolic arrests in children.⁵

ASSESSMENT OF SUCCESSFUL PACING

The Emergency Physician must assess the patient for both electrical capture and associated mechanical capture. **Successful capture is characterized by a wide QRS complex, since it is ventricular in origin, and a broad T wave.** It is easy to mistake the wide, slurred afterpotential following an external pacing spike for electrical capture. **Electrical capture is best judged by the presence of a consistent ST segment and T wave after each generated pacer spike (Figure 41-6C).** Paced beats below the patient's intrinsic cardiac rate may not produce an associated QRS complex (Figure 41-6B), and electrical capture is not achieved. The pacing rate must be increased to achieve capture. Table 41-1 lists the common causes of failure to capture and suggested solutions.

Mechanical capture must be ensured once electrical capture is achieved. This is done with a palpable pulse rate or arterial catheter blood pressure monitoring.¹¹ The patient will have a pulse rate that is exactly equal to that of the paced rhythm on the cardiac monitor if mechanical capture is achieved. Assess the pulse using palpation of the carotid or femoral artery to avoid confusion with skeletal muscle contractions generated by the pacing current. Mechanical capture has not been achieved if the palpated pulse rate is less than that of the paced rate. Increase the threshold current. Mechanical capture is also achieved when the invasive arterial blood pressure line

FIGURE 41-5. Monitor dials demonstrating separate defibrillation, pacing, electrical current (mA), and heart rate to set for TCP.

FIGURE 41-6. Assessing electrocardiographic capture with TCP. **A.** Intrinsic patient bradycardic rhythm. **B.** No electrical capture as TCP is below the threshold level. **C.** TCP with electrical capture.

demonstrates a pulse rate that is exactly equal to that of the paced rhythm on the cardiac monitor.

Threshold current values will vary depending on the clinical situation. Transcutaneous pacing thresholds tend to be lowest in healthy individuals or in patients with minimal hemodynamic compromise. The threshold is usually in the range of 40 to 80 mA.^{21,36} Most patients are paced using a current in the range of 20 to 140 mA.⁸ No clear correlation has been established between the pacing threshold and patient age, weight, body size, chest diameter, or etiology of heart disease.^{8,36,37} Thresholds are usually elevated following thoracic

surgery; in patients with chronic obstructive pulmonary disease, a pneumothorax, a pericardial effusion, or heavy thoracic chest wall musculature; and after positive-pressure ventilation.⁸

Success rates in achieving ventricular capture vary widely depending on the setting where TCP is being used. Success rates appear to be highest (over 90%) when TCP is used prophylactically or early (e.g., within 5 minutes of bradycardic arrest).⁸ A 78% success rate was reported in diverse clinical situations.⁸ **The time to the initiation of TCP largely determines the success rate. There can be changes in the pacing threshold leading to capture failure with prolonged pacing.** Failure to capture may be encountered due to a variety of reasons.

Ultrasound has been used as a method to confirm electrical and mechanical capture.³⁸⁻⁴¹ It can be used to determine the ventricular contraction rate. The patient will have a heart rate exactly equal to that of the set paced rate if mechanical capture is achieved. This eliminates the artifact seen on the ECG monitor from chest wall muscle contractions.

AFTERCARE

The most important assessment in the aftercare period is to ensure continuous electrical and mechanical capture. This should be accomplished by frequent checks of the cardiac monitor, palpation of a pulse, and measurement of a blood pressure. This is more easily established using an arterial line. **Threshold current values can change with prolonged TCP.** The system can be somewhat tenuous in practical use, and frequent checks are advisable. Insert a transvenous cardiac pacer in the Emergency Department or arrange with a Cardiologist to place one in the catheterization lab if the patient requires prolonged TCP.

Patient comfort must be continuously reassessed. Pain can be due to chest wall muscle contractions or other causes (**Table 41-2**). **Do**

TABLE 41-1 Common Causes of Failure to Capture and Suggested Solutions	
Etiology	Solution
Suboptimal electrode placement	Reposition electrodes to avoid the spine, scapula, and sternum
Negative electrode placed posteriorly	Place negative electrode anteriorly over the cardiac apex or the V ₃ lead position
Poor skin–electrode contact	Clean skin of sweat and debris; dry skin thoroughly; trim hair
Faulty electrical contact	Check electrical connections
Generator battery depletion	Change battery; plug generator into an electric outlet
Increased intrathoracic air	Reduce positive–pressure ventilation; relieve pneumothorax
Pericardial effusion	Pericardiocentesis; pericardial window
Myocardial ischemia/metabolic derangement	Cardiopulmonary resuscitation; ventilation; correct acidosis; correct hypoxia; correct electrolyte abnormalities
High threshold	Use stimuli of longer pulse width; shave hair for improved pad attachment; apply pressure to pads; apply pads with fresh gel

Source: Modified from Ellenbogen KA, Wood MA: *Cardiac Pacing and ICDs*, 5th ed. Oxford: Blackwell, 2008.

TABLE 41-2 Causes of Painful Transcutaneous Pacing and Suggested Solutions

Etiology	Solution
Conductive foreign body beneath electrode	Remove foreign body
Electrode over skin abrasions (shaved)	Reposition electrodes; avoid shaving beneath electrodes
Apprehensive patient or low pain tolerance	Administer parenteral narcotics and/or benzodiazepines
Sweat or salt deposits, saline, conductive jelly, blood, or vomitus on skin	Cleanse and dry skin
High threshold to pacing	Use longer pulse-width stimuli
Thoracic wall muscle contractions	Intravenous sedation and/or analgesics

Source: Modified from Ellenbogen KA, Wood MA: *Cardiac Pacing and ICDs*, 5th ed. Oxford: Blackwell, 2008.

not assume that pain is from chest wall muscle contractions until other etiologies are ruled out. Repeated doses of a sedative and/or analgesics may be required to ease the discomfort of chest wall muscle contractions. **Periodically assess the skin under the electrodes for burns or damage.** Reposition the electrodes if skin erythema or any signs of a burn are present. **This is especially important in patients who are young children, unconscious, or have altered mental status as they cannot complain of pain.**

COMPLICATIONS

There are few major complications related to this procedure.⁴² One of the most important complications to consider is the failure to recognize underlying rhythm changes in the patient or loss of capture (i.e., electrical or mechanical) once the procedure is completed. A rhythm change to ventricular fibrillation is easy to miss and can be ascribed to pacing artifacts and chest wall muscle contraction. These complications are mitigated by close patient and monitor surveillance during TCP. Tachydysrhythmias related to TCP have been documented, but the overall risk for this complication is considered small.^{20,23} Myocardial damage from TCP has been examined in animals and humans without significant findings.^{2,43,44} Thermal injury to the skin from the electrodes is a known complication, especially in situations of prolonged TCP, and can be minimized with careful observation and electrode adjustments.⁴⁵ Pain is the most commonly reported complication (Table 41-2) and needs to be continually addressed. The most common etiology of the pain is from chest wall muscle contractions.

SUMMARY

TCP is a temporary method of cardiac pacing in patients with severe symptomatic bradyarrhythmias due to high-grade AV blocks, sinus node dysfunction, or bradyasystolic cardiac arrest, or rarely for overdrive pacing to suppress ventricular and supraventricular tachyarrhythmias. It is comparatively easy to perform and requires minimal training. Once capture is achieved, the current output should be set at a level slightly higher than the pacing threshold. Successful TCP can be established in 80% to 90% of patients. Discomfort and pain due to muscle contraction are the most common side effects. Most patients will require sedation and/or analgesics to tolerate TCP for a significant length of time.

Transthoracic Cardiac Pacing

Chirag N. Shah, Guillermo Ortega, and Daniel S. Morrison

INTRODUCTION

Transthoracic cardiac pacing is a historic technique of pacing the heart with an electrode introduced percutaneously into the ventricular cavity using a needle trocar introducer. There is sparse literature on transthoracic cardiac pacing, its benefits, and complications. Transthoracic pacing was a faster alternative to transvenous pacing in the patient with an acutely unstable dysrhythmia. The advent of effective and efficient transcutaneous pacing has made the indications for transthoracic pacing extremely rare. The technique of transthoracic pacing is included in this text because it is occasionally performed in situations where transcutaneous pacing is unavailable or ineffective.¹⁻³

The history of electrical stimulation of the heart dates to 1862 when Walsh discussed the possibility of causing the heart to contract through stimulation of the sympathetic nervous trunk by an induced current.⁴ It was largely understood by 1910 that the neuromuscular mechanism of the heart was electrically dependent. A needle electrode was used in 1928 to carry stimulating current directly to heart muscle.⁵ The first successful clinical application of external cardiac pacing was in 1952 with the resuscitation of two patients in asystole following bradycardia from a high-degree atrioventricular (AV) block.⁶ It was concluded that external cardiac pacing was a safe and effective means of resuscitating ventricular standstill. The devices caused significant chest pain, skeletal muscle spasm, and superficial skin burns and disrupted

electrocardiogram (ECG) monitoring.⁶ The quest for alternative pacing modalities continued with the refinement of the transesophageal technique in 1957.⁷ The emergency use of a lumbar puncture needle introduced 5 mm into the myocardium, through which a conducting wire was introduced, was used to produce transthoracic cardiac pacing.⁸ A transvenous wire catheter was passed in 1959 that successfully applied an electrical current to the endocardial surface of the right atrium.⁹ Transvenous pacing subsequently became the most widely accepted method of emergency cardiac pacing until the reemergence of a modified external pacing system in 1981.¹⁰

ANATOMY AND PATHOPHYSIOLOGY

The heart is the only muscle of the body that generates its own electrical impulses. The initial cardiac impulse starts in the right atrium at the sinoatrial (SA) node. The sympathetic and parasympathetic nervous systems control the rate of impulse generation at the SA node. The electrical stimulus is conducted along the internal conduction pathways of the heart to the muscular atrial and ventricular walls. A delicate balance between electrolyte flux to create action potentials, myocardial integrity to allow impulses to become contractions, and an intact conduction system must be maintained. The blood supply to the conduction system of the heart originates from the right coronary artery. Arrhythmias and conduction delays are often the result of inadequate blood flow to the heart due to ventricular infarction and coronary artery occlusion.

INDICATIONS

Transthoracic cardiac pacing is a simple procedure and can be accomplished rapidly. The indications for transthoracic pacing appear extremely limited. There is only a 40% success rate in achieving pacing by the transthoracic route.¹¹ Transcutaneous pacing success rates of greater than 80% have been routinely demonstrated.¹² **Transthoracic pacing should be reserved to clinical situations where there is no transcutaneous pacing available, when transcutaneous pacing in the perimorbid patient has been unsuccessful, or when the placement of a transvenous pacer is thought to be too time consuming.**^{13,14}

Unstable bradydysrhythmia is the obvious indication for emergency cardiac pacing. Several case reports document successful transthoracic pacing in patients with asystolic arrest.¹ Other studies document successful pacing out of asystole in patients with in situ pacemakers.¹⁵ A study of approximately 300 patients with witnessed or early asystole demonstrated no improved outcome with early transcutaneous pacing intervention by first response emergency medical personnel.¹⁶ It was concluded that emergency transthoracic cardiac pacing has a very low success rate in asystole but may be lifesaving in the rare case.

Transthoracic cardiac pacing would be most effective following cardiac arrest from primary cardiac disease.¹³ Transthoracic cardiac pacing may not be effective in cardiac arrest secondary to hypovolemia (e.g., trauma), severe electrolyte abnormalities, acid-base abnormalities, sepsis, or drug intoxication. Transthoracic cardiac pacing may be lifesaving when bradycardia or asystole secondary to prolonged ischemia during hypovolemic shock persists despite correction of the underlying pathology.

The use of transthoracic cardiac pacing in unstable patients is more controversial. Transthoracic cardiac pacing may be considered in patients with unstable sinus bradycardia, junctional bradycardia, atrial fibrillation with high-degree AV block, and AV dissociation with inadequate ventricular response.¹³

CONTRAINDICATIONS

Transthoracic cardiac pacing should not be performed in hemodynamically stable awake patients. It is contraindicated if the patient has a dysrhythmia that could be quickly and easily corrected by medication, cardioversion, or electrical defibrillation.

Transthoracic cardiac pacing may be ineffective in electromechanical dissociation and ventricular fibrillation. The heart becomes insensitive to pacemaker activity in ventricular fibrillation.¹⁷⁻²⁰ Any mode of pacing is ineffective in pulseless electrical activity.¹⁷⁻²⁰ A pacemaker is ineffective in patients with prolonged cardiac arrest.¹⁶ Patients with cardiac arrest for more than 5 to 10 minutes could not be resuscitated with the use of cardiac pacing, but patients who had pacemakers placed within 2 to 4 minutes after cardiac standstill were successfully resuscitated.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Transthoracic cardiac pacing wires/kit
- Pacemaker generator
- 10 mL syringe
- Water-soluble lubricant
- Sterile gauze 4×4 squares
- Sterile drapes
- Sterile gloves and gown
- Face mask
- Cap
- Ultrasound machine (optional)
- Ultrasound transducer (optional)
- Sterile ultrasound gel (optional)
- Sterile ultrasound transducer cover (optional)

The instrumentation for transthoracic cardiac pacing comes in a sterile, one-time-use, prepackaged kit. The equipment consists of a 37 cm bipolar J-shaped pacing wire, a 6 inch 18 gauge blunt-end steel cannula with a pointed inner trocar, and a plastic electrical connector that accepts the pacing wire and can be attached to a battery-powered external pacemaker generator (**Figure 42-1**). The cannula and trocar function as a catheter-over-the-needle.

PATIENT PREPARATION

Explain the risks, benefits, and alternative procedures to the patient if they are awake and/or their representative. Obtain an informed consent for the procedure and place this in the medical record. A signed consent is not required, and time is often lacking to obtain

FIGURE 42-1. Equipment required for transthoracic cardiac pacing. **A.** Electrical connector. **B.** Bipolar pacing wire with a sleeve. **C.** Blunt steel cannula with pointed trocar.

a signature. Document in the medical record that the patient was informed of the risks and benefits of the procedure. When performing the procedure on a neonate or child, it is advisable to give the parent the option to leave the room or look away as the procedure can be disconcerting to some parents.

Place the patient supine. Clean the chest and subxiphoid area of any dirt and debris. Apply povidone iodine or chlorhexidine solution to the chest and subxiphoid area. Allow it to dry if time permits. Apply sterile drapes to delineate a sterile field.

Cardiopulmonary resuscitation (CPR) can be continued during most of the procedure but should be stopped while the intracardiac needle is being inserted to avoid possible damage to the lung or myocardium. Full ventilation of the lungs is recommended during subxiphoid cannula placement to depress the diaphragm and minimize the risk of injury to the liver and stomach. Insert a nasogastric tube to decompress the stomach prior to performing the procedure. Fully monitor the patient with a noninvasive blood pressure cuff or arterial line, pulse oximetry, and cardiac monitor. Obtain IV access (e.g., intraosseously, intravenously, or central venously).

The Emergency Physician should prepare themselves and the equipment. Don a cap, mask, sterile gloves, and sterile gown. Open the transthoracic cardiac pacing kit onto a sterile field. Lubricate the trocar liberally and insert it securely into the steel cannula. Prepare the ultrasound transducer if using ultrasound with the procedure. Have an assistant apply ultrasound gel over the footprint of the transducer. Instruct the assistant to place the gel-coated transducer in the sterile cover while you hold it. Have the assistant place sterile ultrasound gel on the patient's upper abdomen and lower chest.

TECHNIQUE

Quickly identify the anatomic landmarks necessary to perform this procedure and determine the approach. The cannula-over-the-trocar can be inserted through the left fifth intercostal space parasternally, 4 cm lateral to the midsternal line, or 6 cm lateral to the midsternal line (**Figure 42-2A**). Aim the tip of the cannula-over-the-trocar toward the second costal cartilage. Alternatively, insert the cannula-over-the-trocar through the left xiphocostal junction and aimed toward either the right shoulder, left shoulder, or sternal notch (**Figure 42-2B**).

If bedside ultrasound is available, identifying the right ventricle via the parasternal approach through the fifth intercostal space may be the technique of choice. Without ultrasound, the simplest and quickest approach is to insert the trocar at the left xiphocostal junction and aimed toward the sternal notch. This technique is described below.

Briefly stop CPR. Insert the cannula-over-the-trocar from the left xiphocostal region at a 30° to 40° angle to the skin and directed toward the sternal notch (**Figure 42-2B**). Advance the cannula-over-the-trocar approximately three-fourths of its length. Hold and stabilize the cannula. Withdraw the trocar. Attach a 10 mL syringe to the cannula. Apply negative pressure to the syringe. The aspiration of blood into the syringe confirms proper positioning of the cannula within the ventricle. If blood is not aspirated, withdraw the cannula and restart the procedure. Placement is ideally confirmed with bedside ultrasound.

Insert the transcutaneous pacing wire. Advance the plastic sheath over the pacing wire until it straightens out and covers the J-shaped end of the pacing wire. Insert the plastic sheath into the cannula hub. Advance the pacing wire through the cannula and into the ventricle. Stop advancing the pacing wire when 4 to 5 cm remains outside the cannula. **No resistance should be felt while the pacing wire is being advanced. The cannula is not within the ventricle if resistance is felt. Remove the cannula and pacing wire as a unit and restart the procedure.** The pacing

Placement of a percutaneous transthoracic cardiac pacemaker. **A.** Parasternal approaches. 5ICS-PS, fifth intercostal space immediately to the left of the sternum; 5ICS-4, fifth intercostal space, 4 cm from the midsternal line; 5ICS-6, fifth intercostal space, 6 cm from the midsternal line. **B.** Subxiphoid approaches. SX-RS, subxiphoid–right shoulder; SX-SN, subxiphoid–sternal notch; SX-LS, subxiphoid–left shoulder.

wire will reform its J-shape when it is inside the ventricle. Hold the pacing wire securely. Withdraw the cannula over the pacing wire. **Do not release the hold on the proximal end of the pacing wire outside the patient's thorax to prevent it from slipping inside the thorax.**

Insert the proximal end of the pacing wire into the plastic connector. Secure it with the screws in the body of the connector. Connect the positive and negative terminals of the plastic connector to the pacemaker generator. Turn on the pacemaker generator. Set the pacing rate at 70 to 90 beats per minute in an asynchronous mode. Set the current output to the maximum milliamperage rate on the pacemaker generator. Demonstrate myocardial capture of the electrical stimulus (i.e., each pacer spike followed by a QRS complex). Lower the current output until 1:1 pacing is lost. Gradually increase the current output to attain stimulation threshold when 1:1 capture is regained. The optimal current output is two to three times the stimulation threshold. Change the mode of the pacemaker to a demand pacemaker with a backup rate of 60 to 70 beats per minute. A complete description of the functioning of the pacemaker generator is reviewed in Chapter 41.

Pacer spikes should be visualized on the ECG tracing on the cardiac monitor. Check the contact between the pacer wire and electrical connector if pacer spikes are not visualized. Check the batteries in the pacemaker energy source. Pacer spikes not followed by myocardial capture usually indicate inadequate positioning of the pacing electrode. Gently manipulate the transthoracic pacemaker wire to change its position.

ASSESSMENT

The positioning of the pacing wire should be verified by chest radiograph or bedside ultrasound.²¹ Ideal placement of the pacing wire should be at the mid-myocardial septum to preserve right ventricle performance while preventing dyssynchrony of the ventricles. This is important to consider as failing to do so can result in a lower ejection fraction from the left ventricle and impaired blood flow to the coronary arteries.^{22,23} Obtain a 12-lead ECG to document capture and to verify the positioning of the pacing wire based on the QRS configuration in the ECG. **A left bundle branch block**

configuration will be demonstrated on the ECG if the pacing wire is in the right ventricle. A pacing wire in the right atrium or left ventricle will still pace the myocardium, but the ECG will have a different QRS configuration. **An atrially positioned pacing wire will be ineffective if the patient is in AV block.**

AFTERCARE

Secure the pacing wire to the skin with 3–0 nylon suture. A transvenous or permanent pacemaker should be inserted as soon as possible. Consult a Cardiologist immediately and admit the patient to an Intensive Care Unit.

COMPLICATIONS

Analysis of the complications of transthoracic cardiac pacing is greatly limited by the paucity of short-term survivors and the absence of radiographic or pathologic evaluation of nonsurvivors. Complications include laceration of the right atrium, ventricles, coronary arteries, great vessels, vena cava, stomach, liver, and lung. Hemopericardium is a ubiquitous finding in some autopsy studies, and cardiac tamponade has been reported.^{24,25} Pneumothorax has been reported and is a particular concern in persons receiving positive-pressure ventilation.²⁶

SUMMARY

The technique of transthoracic cardiac pacing has been clinically feasible for more than 50 years, but there is extremely limited literature supporting its regular use. The technique is simple and can be performed in less than a minute. However, it carries a high risk for multiple significant complications. There is no clear understanding of the effect of transthoracic cardiac pacing on the outcome of cardiac arrest. Most of the available information comes from animal studies, retrospective analysis, and anecdotal data.

Transthoracic cardiac pacing may be useful in the setting of cardiac arrest with asystole or a pulseless idioventricular rhythm. It may be performed if transcutaneous cardiac pacing is not available or effective. Transthoracic cardiac pacing can be initiated promptly

in the hemodynamically unstable patient with drug-resistant bradycardia producing cardiovascular collapse or lethal escape rhythms whose clinical condition does not warrant a delay to insert a transvenous pacing catheter. Bedside ultrasound may be useful in guiding and confirming the appropriate placement of the transthoracic pacing device.

Transvenous Cardiac Pacing

Myles C. McClelland, Thuy Nguyen, and Alfred Coates III

INTRODUCTION

Emergency cardiac pacing can be accomplished by several methods. These include epicardial, esophageal, transcutaneous, transthoracic, and transvenous pacing. Emergency cardiac pacing can be a temporizing and lifesaving technique that should be familiar to Emergency Physicians.¹⁻³ It will allow the patient to maintain a cardiac rhythm while providing oxygen and nutrients to the vital organs.

The earliest use of electricity to stimulate the heart can be found in an essay written in the late 1700s.⁴ It discusses the use of electric current and artificial ventilation to revive victims of drowning. Transvenous pacing was first attempted on dogs in 1905. The transvenous approach in humans was developed in 1959 using a stiff pacing wire. Semiflexible pacing wires were developed in 1964 and were placed using fluoroscopic guidance. The demand pacemaker was developed in 1966. Catheter technology improved with the semi-floating catheter in 1969 and the balloon tip catheter in 1973. The technology and technique have since been developed to allow successful transvenous cardiac pacing in humans. It involves the placement of a pacing wire through the central venous circulation and into direct contact with the myocardium of the right ventricle.

ANATOMY AND PATHOPHYSIOLOGY

The heart is the only muscle of the body that generates its own electric impulses (**Figure 43-1**). Its automaticity and subsequent rhythmic contractions propel blood to the tissues of the body. The initial cardiac impulse starts in the right atrium of the heart at the sinoatrial (SA) node. The sympathetic and parasympathetic nervous systems control the rate of impulse generation at the SA node. The electric stimulus is conducted along the internal conduction pathways of the heart to the muscular atrial and ventricular walls. A delicate balance between electrolyte flux to create action potentials, myocardial integrity to allow impulses to become contractions, and an intact conduction system must be maintained. **Conduction system problems are often the result of inadequate blood flow to the heart due to ventricular infarction and coronary artery occlusion.** The blood supply to the conduction system of the heart

FIGURE 43-1. Conduction system of the heart. (Used from Madhero88, <https://commons.wikimedia.org>.)

FIGURE 43-2. Common sites for introducing a transvenous pacing catheter. **A.** The right internal jugular vein. **B.** The left subclavian vein.

usually originates from the right coronary artery. **Occlusion of the right coronary artery can result in arrhythmias and conduction delays.**

A transvenous pacing catheter may be introduced through the femoral, internal jugular, or subclavian veins.⁵ **The right internal jugular vein and left subclavian vein are the recommended sites (Figure 43-2).** These routes allow a more direct and easy access for the pacing catheter to enter the right ventricle. The right internal jugular vein is preferred. It allows a relatively straight line of access through the superior vena cava and right atrium into the right ventricle.⁶ The left subclavian vein is a good second choice if access to the right internal jugular vein is not accessible. The left subclavian vein is the site of choice for a permanent pacemaker if required. Thus, many will not use this site. The other routes are technically more difficult to use and often require fluoroscopy for proper placement of the pacing catheter. The right subclavian vein and left internal jugular vein require several turns for the pacing catheter to navigate. This increases the difficulty of entering the right ventricle.

The femoral vein is often used in infants and younger children to insert a transvenous cardiac pacing catheter (**Figure 43-3**). Insertion of the pacing catheter via the femoral vein often requires fluoroscopy. The disadvantages of using the femoral vein for vascular access include the potential for deep venous thromboses, infection, restricted mobility, and thrombophlebitis. The infant and young child's relatively large head and short neck make access to the internal jugular vein difficult. The subclavian vein in an infant and child is situated more posterior to the clavicle than in an adult. This makes it more difficult to access the subclavian vein while increasing the chance of causing a pneumothorax.

Pacing the left ventricle through a femoral artery approach has been suggested in emergent situations.⁷ These instances usually involve the inability to obtain venous access due to scarring, previous procedures, or venous thrombosis. This nonstandard approach has been used successfully in situations when transvenous cardiac pacing was not feasible.^{7,8} This technique cannot currently be recommended for routine use but is a potential alternative technique for use in dire circumstances.

INDICATIONS

The indications for transvenous pacing are the same as for other methods of cardiac pacing.^{1,9-11} Patients with atrial or ventricular arrhythmias that require overdrive pacing, atrioventricular

FIGURE 43-3. The femoral vein is used in children to access the central venous circulation and introduce a transvenous pacing catheter.

dissociation, bradycardia unresponsive to drug therapy, and conduction delays that may degenerate into complete heart block can benefit from transvenous pacing.^{4,6,12-14} Specific bradycardic conditions that may benefit from transvenous cardiac pacing include atrial fibrillation with a slow ventricle response rate, second-degree heart block, sick sinus syndrome, sinus arrest, sinus bradycardia, sinus node dysfunction, symptomatic bradycardia, and third-degree heart block. Patients with myocardial infarctions or new heart blocks may require cardiac pacing. Tachyarrhythmic conditions that may benefit from overdrive cardiac pacing include atrial fibrillation, atrial flutter, supraventricular tachycardias not responsive to drugs or cardioversion, torsades de pointes, ventricular tachyarrhythmias due to drug toxicity (e.g., quinidine or digoxin), and Wolfe-Parkinson-White tachyarrhythmias. Transvenous pacing may be used in patients who do not tolerate transcutaneous pacing or whose heart does not capture with transcutaneous pacing. A transvenous pacing catheter may be temporarily inserted to pace the myocardium if a permanent pacemaker is not functioning. A more complete discussion on the indications for cardiac pacing is presented in Chapter 41 on transcutaneous cardiac pacing.

Transcutaneous pacing is a first option that is easy to initiate. It may be replaced with transvenous pacing. Transcutaneous pacing pads will not stick very well to hairy or diaphoretic patients. Avoid transcutaneous pacing over an implantable defibrillator. Transcutaneous pacing requires a lot of energy to the chest wall. This may be uncomfortable to the patient. Transvenous pacing avoids giving the patient narcotics, which are needed for transcutaneous pacing pain, resulting in possible blood pressure drops. Pulses are easier to palpate using transvenous pacing. Chest wall artifacts with transcutaneous pacing may interfere with arrhythmia detection.

CONTRAINDICATIONS

Do not insert a transvenous pacing catheter into the heart in patients who are hypothermic. These patients have increased irritability of the myocardium and are prone to life-threatening ventricular fibrillation if the pacing wire contacts the heart muscle.^{4,6} Relative contraindications to the placement of a transvenous pacing catheter include digoxin toxicity and other drug ingestions that may increase the irritability of the myocardium. Patients who are asystolic for extended periods of time have a low likelihood of successful resuscitation.⁶ These patients are not candidates for a transvenous pacer. Do not insert a pacing catheter through infected skin or areas with any skin lesions (e.g., burns, cellulitis, or dermatides) to prevent possible infections (e.g., endocarditis, myocarditis, or sepsis). Avoid areas that contain subcutaneous devices (e.g., permanent pacer, AICD, and Port-A-Cath) and choose an alternative site. Do not prophylactically place a transvenous pacing catheter in a patient with a myocardial infarction unless they have a new heart block or symptomatic bradycardia. Patients taking anticoagulants, with bleeding diatheses, or on concurrent thrombolytic therapy should not have a transvenous pacing catheter placed except in emergent situations due to the risk of hemorrhage and bleeding complications. Other relative contraindications include the presence of a prosthetic tricuspid valve, coagulopathy, distortion of local and anatomic landmarks, and known abnormal cardiac anatomy.

EQUIPMENT

- Flexible, flow-directed, transvenous cardiac pacing catheter (Figure 43-4)
 - 3 or 4 French for infants and children
 - 5 or 6 French for adolescents and adults
- Pacemaker generator (Figure 43-5)

FIGURE 43-4. An example of a flexible, flow-directed transvenous pacing catheter.

- Spare battery for pacemaker
- Sterile drapes
- Sterile gloves and gown
- Face mask with face shield or goggles
- Hat
- Povidone iodine or chlorhexidine solution
- Cordis or Swan introducer catheter kit, one size larger than the pacing catheter
- Cardiac monitor
- Local anesthetic solution
- 3–0 nylon suture
- Gauze squares
- Skin tape
- Alligator clips and connecting wire
- Towels for shoulder rolls
- Defibrillator
- Airway management equipment
- Resuscitative drugs
- Ultrasound (US) machine
- US transducer, 3.5 MHz curvilinear or cardiac array
- Sterile US gel
- Sterile US transducer covers

Transvenous cardiac pacing kits are commercially available. They contain the central venous introducer catheter, transvenous pacing wire, and all the required supplies except the pacemaker generator. These single-use and disposable kits are convenient and worth the expense so that time is not expended gathering multiple kits and supplies in an emergent situation when time may be of the essence.

The pacemaker generator is a simple device. Examples are seen in Figure 43-5. Newer models of pacemaker generators have digital displays and other more sophisticated pacing options but function essentially the same as older models. **The Emergency Physician must be familiar with the pacemaker generator and its use prior to needing it in an emergent situation.** The on/off switch is used to turn the unit on. In the “on” position, a spring-loaded safety prevents the unit from accidentally being turned off. The rate-control dial allows adjustments to the number of pacing stimuli per minute. The upper rate limit is often inadequate if overdrive pacing is required. A pacemaker generator with higher rates for overdrive

A

B

C

FIGURE 43-5. Examples of pacemaker generators.

pacing is available. These are rarely kept in the Emergency Department but are usually available from the hospital catheterization lab. The pace indicator light is illuminated whenever a pacing stimulus is generated. The sense indicator light is illuminated whenever a cardiac impulse is sensed. The battery test button is used to determine if the battery has sufficient voltage to operate the pacemaker generator. Depress the battery test button to check the battery voltage. The

D

battery has sufficient voltage if both the pacing and sensing indicator lights illuminate simultaneously. The output control dial is used to adjust the amplitude of the stimulus current. The sensitivity control dial is used to suppress the pulse generator. The bottom of the pacemaker has an access panel under which the battery is located. The top of the pacemaker has positive and negative terminals where the electrodes of the pacemaker catheter insert. Numerous pacemaker

generators are available, each with its own idiosyncrasies. The above instructions and functions are similar to most models.

The pacemaker wires are enclosed in a catheter and come in a variety of lengths and sizes (**Figure 43-4**). They are typically 100 cm in length with markings at intervals of every 10 cm. They come in both flexible and rigid styles. **The rigid catheters are not often used due to the possibility of venous and myocardial perforation.** The flexible catheters have a balloon at the tip. It allows the catheter to flow with the blood into the chambers of the heart.

The pacemaker catheter should ideally be inserted under electrocardiographic (ECG) guidance. An insulated wire with an alligator clip at each end is required. One end is attached to the pacemaker wire and the other to the ECG lead. This allows the Emergency Physician to observe the ECG waveforms as they change while the catheter is advanced through the heart.^{6,12,15} This technique is known as ECG positioning and requires the patient to have intrinsic cardiac activity.

PATIENT PREPARATION

Explain the risks, benefits, and possible complications to the patient and/or their representatives. An appropriate representative may accept for the patient if the patient is unable to consent. The patient may also give verbal consent if they are unable to sign but fully understand the risks and benefits of the procedure. Don full personal protective equipment to protect from contact with the patient's blood and body fluids. This will also partially protect the patient from an iatrogenic infection. **While time is of the essence and this is an emergent procedure, aseptic technique should be followed.**

Place the patient supine and, if possible, in the Trendelenburg position. Place the patient on continuous pulse oximetry, cardiac monitoring, and supplemental oxygen. Establish peripheral intravenous access. Clean and prep the skin in a sterile fashion with povidone iodine or chlorhexidine at the site chosen to access the central venous system. Place rolled towels under the patient's shoulders if the internal jugular vein or the subclavian vein is being used as the site of vascular access. Turn the patient's head to the opposite side of venous access. Apply sterile drapes to fully cover the patient except the site used for vascular access.

TECHNIQUE

Access the central venous circulation by placing a Swan or Cordis introducer catheter sheath. Some authors recommend using the supraclavicular approach for central venous access.¹⁶ This approach may decrease complications due to well-defined surface landmarks, high success rates of vascular access, minimal interference with other procedures, location away from the pleural dome, avoidance of scarring and thrombosis from previous central venous access attempts, minimization of catheter movement, and having a straight path into the right ventricle. Refer to Chapter 63 for the complete details on inserting central venous catheters.

Prepare the pacing catheter (**Figure 43-6**). Attach the precordial lead V_1 to the pacemaker catheter negative terminal. This is accomplished using an insulated wire with an alligator clip at each end. Attach one alligator clip to the negative pacemaker wire. Attach the other alligator clip to the V_1 lead of the ECG monitor. Inflate the pacing catheter balloon with 1.5 mL of air in a container of sterile saline to assess the integrity of the balloon. The presence of bubbles in the saline indicates a balloon leak. Turn on the ECG monitor and set it to lead V_1 . Touch the tip of the pacing catheter and observe the monitor to confirm that the monitor is recording. A large pressure wave should be seen that soon returns to baseline.

FIGURE 43-6. The negative pacemaker terminal is connected to an insulated wire. The insulated wire will be connected to the ECG lead V_1 .

Insert the pacemaker catheter through the rubber diaphragm of the central venous introducer sheath. Advance the catheter 10 cm through the sheath. This ensures that the pacing catheter balloon is past the introducer catheter and within the vascular system. Inflate the balloon with 1.5 mL of sterile saline. **Slowly advance the catheter while always observing the ECG monitor (Figure 43-7).** The P wave and the QRS complex are both small in amplitude and inverted in the subclavian or internal jugular vein (**Figure 43-7A**). The P wave increases in amplitude but is still inverted while the QRS complex is unchanged in the superior vena cava (**Figure 43-7B**). A large P wave with a negative polarity and a small QRS complex will be observed when the pacing catheter reaches the right atrium (**Figure 43-7C**). Continue to advance the catheter. The P waves become upright and the QRS complex increases in amplitude as the lower atrium is entered (**Figure 43-7D**). Continue to advance the catheter into the right ventricle. **The QRS complex should appear normal on the V_1 lead.** The P waves are upright with a large-amplitude QRS complex when the catheter is floating freely in the right ventricle (**Figure 43-7E**). Stop advancing the catheter once the right ventricle is entered and deflate the balloon. Slowly advance the catheter until ST-segment elevation is observed (**Figure 43-7F**). This indicates that the catheter is abutting the right ventricular wall.

The transvenous pacing catheter may occasionally not enter the right ventricle, or it may advance past the right ventricle (**Figure 43-8**).¹⁷ The amplitude of the P wave and QRS complex will decrease if the catheter exits the right atrium and enters the inferior vena cava (**Figure 43-7G**). Withdraw the catheter several centimeters until the atrial waveforms are again seen (**Figures 43-7C and D**) and then readvance the catheter. The P wave will become negative and the QRS amplitude will decrease if the catheter exits the right ventricle and enters the pulmonary artery (**Figure 43-7H**). Withdraw the catheter several centimeters until the right ventricle waveforms are again seen (**Figures 43-7E**) and then readvance the catheter.

Connect the pacemaker generator to the catheter (**Figure 43-9**). Disconnect the negative terminal of the pacemaker catheter from the ECG lead. Connect the pacemaker catheter terminals on the proximal end of the catheter to the negative and positive terminals of the pacemaker generator. **The positive (+) lead connects to the proximal port on the pacemaker generator. The negative (-) lead connects to the distal port on the pacemaker generator.** Set the pacemaker generator on demand mode with a rate of 70 to 80 beats per minute.

FIGURE 43-7. Typical ECG tracings seen with the transvenous pacing catheter within the different anatomic sites. **A.** The subclavian or internal jugular vein. **B.** The superior vena cava. **C.** The high right atrium. **D.** The low right atrium. **E.** Free floating in the right ventricle. **F.** Abutting the right ventricular wall. **G.** The inferior vena cava. **H.** The pulmonary artery.

Start with 5 mA of energy on the output dial. Turn on the pacemaker. Increase the energy until capture is seen on the monitor. This is signaled by pacing spikes and a wide QRS complex in lead V_1 in a left bundle branch pattern. **Decrease the pacemaker generator output to just below where pacing stops once capture is attained. This is known as the threshold point. Resume pacing at 2 mA above the threshold point.**⁶

ULTRASOUND-GUIDED TECHNIQUE

It is often difficult to successfully place the tip of the pacing catheter into the apex of the right ventricle. Lead placement can be guided and confirmed with the assistance of ultrasonography.^{18,19} The pacing electrode is easily visible on US, and its correct position can be

confirmed (**Figure 43-10**). Aguilera and colleagues reported success in eight of nine patients in whom US-guided transvenous pacing was attempted in the Emergency Department.¹⁹ Initial misplacement of the electrode was visualized in three patients and allowed correct repositioning. They concluded that US has promising potential use as an adjunct in emergency cardiac pacing. US can delineate the right ventricle as well as provide quick and noninvasive confirmation of lead placement. It is useful as an aid to detecting and repositioning misplaced pacer leads. Consider using US in conjunction with ECG guidance given the time-sensitive nature of transvenous pacing.

The subxiphoid US view is preferred because it allows visualization of the right atrium and right ventricle. It is a view easily obtained with the patient in the supine position. The subxiphoid view is likely

A

B

FIGURE 43-8. The transvenous pacing catheter loops in the inferior vena cava and then enters the heart. **A.** Radiograph. **B.** US. (Used with permission from reference 17.)

FIGURE 43-9. The transvenous pacing catheter connected to the pacemaker generator.

FIGURE 43-10. Subxiphoid cardiac US image. The transvenous pacing electrode (*large arrow*) is a linear hyperechoic structure passing through the right ventricle to its apex. The interventricular septum is denoted by the *small arrows*.

to be the cardiac window with which Emergency Physicians are most familiar and comfortable. The transvenous pacing electrode is a strong reflector of ultrasound waves and will appear as a linear hyperechoic structure (**Figure 43-10**).¹⁹ The electrode can be seen passing through the right ventricle to the apex (**Figure 43-10**). The apical cardiac view is an option. Obtaining an apical view is more technically difficult and is preferentially performed with the patient in the left lateral decubitus position, which may not be practical. **Care must be taken not to mistake the ventricular septum or wall for the electrode.**

There are limitations in the use of US. Visualization may be difficult in the obese patient or those with chronic obstructive pulmonary disease and expanded lung volumes. Mechanical heart valves may cause significant artifacts that obscure the images. The pacing catheter often lies in multiple echo planes, making visualization more difficult. The lack of catheter visualization may require multiple repositionings of the catheter. Visualization of the catheter may require tilting of the transducer, looking at several different angles with the transducer, and looking at additional views of the heart. All these maneuvers can result in delays before being able to pace the heart.

Visualize the patient's heart using a subxiphoid US view with a 3.5 MHz curvilinear array transducer. Instruct an assistant to hold the transducer in position while the Emergency Physician performs the procedure. Insert the pacing catheter as described above using the ECG-guided technique. Visualize the pacing catheter using US after it enters the right atrium and as it enters the right ventricle, as also noted by the changing ECG waveforms. Continue to advance the pacing catheter under US guidance until its tip is lodged in the apex of the right ventricle (**Figure 43-10**). This may require manipulation of the pacing catheter and/or US transducer to maintain visualization. Continue the remainder of the procedure as noted in the previous section. Ventricular capture is noted as cardiac contractions on the US monitor that are at the same rate as the pacemaker generator setting.

ALTERNATIVE TECHNIQUE

Blind transvenous catheter placement is an alternative. The pacing catheter is inserted "blindly" and without ECG guidance. This technique is often used when alligator clips are not available to connect

the pacing catheter terminals to the ECG monitor. **Always use a flexible catheter. Never place a rigid catheter blindly due to the risk of myocardial perforation.**

Prepare the catheter. Test the balloon as described previously. Make sure the pacemaker generator is off. Connect the pacemaker catheter terminals to the pacemaker generator. Insert the pacemaker catheter through the rubber diaphragm of the central venous introducer sheath. Advance the catheter 10 cm through the sheath. Inflate the balloon with 1.5 mL of sterile saline.

Turn on the pacemaker. **Set the pacemaker on demand mode with a rate twice the patient's native heart rate.** This usually ranges from 80 to 120 beats per minute. Set the output dial to 1.5 to 2.0 mA.

Advance the catheter while observing the sensing indicator light. The sensing indicator will illuminate with every other native heartbeat when the catheter enters the right ventricle. Stop advancing the catheter. Deflate the balloon. Increase the output dial to 10 mA. Slowly advance the catheter until ventricular capture occurs on the cardiac monitor. **Electrical capture is indicated when the ECG monitor attached to the patient's skin by electrodes shows pacer spikes and the development of wide QRS complexes. Do not advance the catheter more than 10 cm past the point where the sensing indicator began to illuminate.** Withdraw the catheter and rotate it 90° if ventricular capture is not successful within 10 cm. Readvance the catheter up to 10 cm. The pacemaker generator output may be set at 20 mA and the pacing catheter readvanced. Continue to repeat the process until ventricular capture is successful. Slowly decrease the ventricular rate to 70 beats per minute once capture occurs. Decrease the pacemaker generator output to 2 mA above the threshold point.⁶

This blind procedure can be modified to be used with US. Visualize the pacing catheter after it enters the right ventricle. Use US to help guide the tip of the pacing catheter into the apex of the right ventricle or to confirm proper positioning of the pacing catheter (Figure 43-10).

ASSESSMENT OF SUCCESSFUL PACING

The Emergency Physician must assess the patient for electrical capture and mechanical capture when considering if the procedure was successful.² Successful capture is characterized by a wide QRS complex, since it is ventricular in origin, and a broad T wave. It is easy to mistake the wide, slurred afterpotential following an external pacing spike for electrical capture. **Electrical capture is best judged by the presence of a consistent ST segment and T wave after each generated pacer spike (Figure 43-7C).** Paced beats below the patient's intrinsic cardiac rate may not produce an associated QRS complex (Figure 43-7B) and electrical capture is not achieved. The pacing rate must be increased to achieve capture in this situation.

Mechanical capture must be ensured once electrical capture is achieved by a palpable pulse rate or arterial catheter blood pressure monitoring. The patient will have a pulse rate that is exactly equal to that of the paced rhythm on the cardiac monitor if mechanical capture is achieved. Assess the pulse using palpation of the carotid or femoral artery to avoid confusion with skeletal muscle contractions generated by the pacing current. **Mechanical capture has not been achieved if the palpated pulse rate is less than that of the paced rate.** Increase the threshold current. **Mechanical capture is achieved when the invasive arterial blood pressure line demonstrates a pulse rate that is exactly equal to that of the paced rhythm on the cardiac monitor.**

US can confirm electrical and mechanical capture.^{20,21} Use US to determine the ventricular contraction rate. The patient will have a heart rate that is exactly equal to that of the set paced rate if mechanical capture is achieved. Refer to Chapter 37 for the complete details of cardiac US.

AFTERCARE

Secure the pacing catheter by suturing it to the chest wall. Infiltrate subcutaneously with 2 mL of local anesthetic solution 1 cm from where the catheter exits the central venous sheath. Secure the catheter to the skin using 3–0 nylon. Apply antibacterial ointment to the site where the pacing catheter exits the central venous sheath. Apply an adhesive dressing (e.g., Tegaderm) over the sheath and catheter. Obtain an ECG. It will show the characteristic left bundle branch block pattern. Obtain a postprocedural chest radiograph to assess the catheter position and to rule out an iatrogenic pneumothorax or hemothorax. Admit the patient to an Intensive Care Unit. Consult a Cardiologist for possible permanent pacemaker placement.

The most important assessment in the aftercare period is to ensure continuous electrical and mechanical capture. This should be accomplished by frequent checks of the cardiac monitor, palpation of a pulse, and measurement of a blood pressure. This is more easily established using an arterial line (Chapter 72).

COMPLICATIONS

Perforation of the ventricular septum, the atria, or the free wall of the ventricle may occur during catheter placement (Figure 43-11).^{22,23} This is more commonly seen with the rigid catheters and in elderly patients with kyphoscoliosis in whom right heart catheterization can be more difficult.²⁴ Septal perforation should be suspected if the pattern on the ECG changes from a left to a right bundle branch block.^{6,25} Septal perforation should be suspected if there is an increase in the pacing threshold. Ventricular perforation can present as a failure to capture or as cardiac tamponade. A friction rub may be audible on cardiac auscultation if a perforation is present. Perforation of the inferior wall could stimulate and pace the diaphragm.^{6,25} The treatment for these complications is to withdraw and reposition the pacing catheter. **The patient must then be evaluated and observed for the possibility of cardiac tamponade.**

Multiple attempts to place the tip of the pacing catheter in the apex of the right ventricle can result in complications. Movement of the catheter forward and backward can form a loop within the

FIGURE 43-11. A pacing lead perforated the right ventricle and caused a pericardial effusion. (Used with permission from reference 23.)

A

B

FIGURE 43-12. The pacing catheter can form a loop within the right ventricle. **A.** Schematic. **B.** Radiograph. (Used with permission Charles Bruen, MD, and www.ressusreview.com.)

cardiac chambers (**Figure 43-12**). The catheter tip can advance through the loop and result in a knot being formed in the pacing catheter. This requires an Interventional Cardiologist to unknot and remove the catheter in the cardiac catheterization laboratory under fluoroscopic guidance.

Advancement of the pacing catheter through a patent foramen ovale will result in left ventricular pacing.^{26,27} This is recognized as a right bundle branch pattern on the ECG. US can be used to visualize the pacing catheter in the left ventricle or the lack of it in the

right ventricle. Radiographic or angiography studies will be needed to determine if the tip of the catheter passed through the foramen or perforated the interatrial or interventricular septum. Blood clots can form anywhere along the transvenous catheter. These clots can break loose and flow through a patent foramen ovale to cause a transient ischemic attack or stroke.

The transvenous catheter can be inserted too far or past the heart. The catheter can be in the inferior vena cava or loop in the inferior vena cava (**Figure 43-8**).¹⁷ The heart waveform may be lost once the tip of the catheter enters the inferior vena cava.

Cardiac arrhythmias may occur during insertion of the pacing catheter. Ventricular arrhythmias can occur during the procedure and even after the procedure is completed. Immediately withdraw the catheter a few centimeters and observe the rhythm. If it resolves, readvance the catheter. A defibrillator and cardiac resuscitation drugs must be available to facilitate immediate treatment of any rhythm disturbance.^{6,25}

Infection can be a delayed complication. **Always use strict aseptic techniques when inserting the central venous introducer sheath and the transvenous pacing catheter.** There is currently no clinical evidence to suggest that the use of prophylactic antibiotics decreases infections or infectious complications. The use of prophylactic antibiotics cannot be currently recommended. The most common organisms are skin flora. The types of infection can range from cellulitis at the puncture site to myocarditis and florid sepsis.^{6,12,25} Infection requires parenteral antibiotic therapy, the catheter to be removed, and the catheter tip to be cultured. If the pacing catheter is absolutely required, select a new puncture site and insert a new pacing catheter.

The pacing catheter balloon can be a source of complications.^{28,29} Air embolism has been reported. This can be prevented by assessing the balloon for leaks prior to inserting the catheter. Do not overinflate the balloon. An air embolism or a piece of ruptured balloon may obstruct part of the pulmonary circulation. Do not inflate the balloon after it is inserted more than 10 to 15 cm into the ventricle. The vessel may rupture if the balloon is inflated when the catheter tip is in a branch of the pulmonary artery. Forward and backward movement of the pacing catheter with the balloon inflated may result in rupture of the chordae tendineae with subsequent tricuspid regurgitation.

The pacing circuit (i.e., catheter, wires, and pacemaker) can also be a source of complications. The catheter may become dislodged or fractured. The pacemaker may fail due to battery drainage, generator failure, or electrical interference.

Anatomic variations may be present and not known to the patient or the Emergency Physician.³⁰ These include persistent left-sided superior vena cava, congenital lack of a vein, or congenital duplication of a vein.³⁰ Anatomic variations can increase the technical difficulty of the procedure. It might be necessary to use a femoral approach if the internal jugular or subclavian vein approaches are unsuccessful, regardless of the reason.³⁰

Complications related to obtaining central venous access are discussed in Chapter 63. They include air embolism, infection, sepsis, cellulitis, pneumothorax, improper placement, arterial puncture, venous thrombosis, venous thrombophlebitis, and guidewire complications. Complications may be decreased by using the supraclavicular approach rather than the subclavian or internal jugular approaches.¹⁶

EVOLVING TECHNOLOGY

Temporary dual-chamber pacemakers have been made commercially available. An absolute application for this technology has not been validated in an emergency. As our understanding of cardiac disease evolves, emergent applications may be revealed. Dual-chamber

pacemakers allow for AV synchronization. They have demonstrated benefit in pathologies (e.g., carotid sinus syndrome, high-degree AV block, sinus bradycardia, and sinus node dysfunction) and in symptomatic patients (e.g., heart failure, seizure, or syncope). This might provide benefit when AV synchronization is critical or in the rare instance when cardiac outflow is dependent on atrial kick.

The technique for placing a dual-chamber pacemaker is similar to placing a single-lead transvenous pacemaker. The second lead is in the atrium instead of the ventricle. It is important to be familiar with the North American and British pacing societies (NBG) coding system (Chapter 45).³¹ The NBG is a five-letter system for identifying the modes of pacing. The first letter designates which chamber is being paced. The second letter designates which chamber is being sensed. The third letter designates the mode responding to sensing. The fourth and fifth letters are designated for internal pacing modes.

SUMMARY

Placement of a transvenous cardiac pacing catheter can be a life-saving procedure. It is a safe method to electrically stimulate the heart. It is indicated when an unstable rhythm of the heart is refractory to medications and transcutaneous pacing. Proper placement of the pacing catheter is cardinal to its functioning. Recognition of the ECG changes that occur in the different anatomic areas helps to guide its placement. Be aware of the potential complications and their management. This procedure should be mastered by all Emergency Physicians caring for critically ill and/or injured patients.

Transesophageal Cardiac Pacing

John Bass and Chad Gorbattin

INTRODUCTION

Cardiac pacing is an essential skill for Emergency Physicians and can be accomplished through a variety of techniques. Transesophageal cardiac pacing is a time-proven and potentially lifesaving procedure. The esophagus has long been considered a noninvasive and useful window to the heart.

The ability to capture and record an electrocardiogram (ECG) transesophageally was first demonstrated by Max Cremer in 1906.¹ This was based on the close anatomic proximity of the cardiac atria to the esophagus. The proximity allows an electrical impulse in the esophagus to be transmitted to the left atrium. Electrode technology and pacing mechanisms have advanced. The ability to identify, stabilize, and terminate atrial dysrhythmias through this minimally invasive procedure persists.² Transesophageal pacing is well-tolerated by patients and effective for temporarily treating patients with atrial rhythm disturbances. This technique provides an additional tool for Emergency Physicians.

ANATOMY AND PATHOPHYSIOLOGY

The heart is the only muscle that produces its own electrical impulse. The electrical impulse originates from the sinoatrial node of the right atrium and is conducted through the heart's intrinsic electrical conducting system to the atria and ventricles to produce coordinated and sequential mechanical contractions (**Figure 39-2**).³ The rate of impulse generation is governed by the sympathetic and parasympathetic nervous systems. The conversion of an electrical impulse to a mechanical action is a delicate balance between chemical signaling, electrolyte shifts, an intact cardiac conducting system, and healthy myocardial tissue. Abnormalities in conduction and resultant arrhythmias may be related to abnormalities in any of these factors. Aberrant conduction system development, impaired myocardium due to decreased blood supply, or impaired myocardium due to infarct often underlies arrhythmias.

The heart is in the anterior thoracic cavity. It is surrounded by the sternum and chest wall anteriorly, the lungs laterally, and in proximity to the esophagus posteriorly. The left atrium is typically the closest point of contact to the esophagus (**Figure 44-1**).⁴ Cadaveric models and imaging analysis show an atri-esophageal distance of typically less than 1 cm, and often only a few millimeters.⁵ This is impacted by individual variability and disease states that may alter cardiac muscle size.

INDICATIONS

Transesophageal cardiac pacing can be a simple and easily initiated procedure. Weigh its use against clinical circumstances. Transesophageal atrial pacing is most frequently used for management of symptomatic bradycardia, termination of atrial fibrillation, and termination of supraventricular tachycardia.^{1,6-11} Sinus node dysfunction or delays in electrical impulse conduction may manifest as bradycardia. End-organ hypoperfusion can occur with decreased cardiac output and result in a variety of symptoms (e.g., altered mental status or fatigue). Use transesophageal pacing to temporarily

FIGURE 44-1. The relationship of the esophageal catheter to the heart. (Used from www.comonswikimedia.org.)

restore a heart rate that is compatible with end-organ perfusion and in preparation for definitive treatment of the underlying condition.

An accelerated heart rate can result in similar symptoms. Such tachyarrhythmias, especially in pediatric patients, are often supraventricular in origin. Transesophageal pacing is a well-tolerated and effective means of suppressing or abolishing inappropriate tachyarrhythmias given the possible complications associated with transvenous access and pacing in pediatric patients (**Figure 44-2**).^{12,13}

Several studies favor the use of transesophageal pacing. A small prospective study showed no difference in conversion rates or procedure duration when comparing scheduled transcutaneous to transesophageal electrical cardioversion for adults with atrial fibrillation.¹⁴ Transesophageal electrical cardioversion in adults has a 97% restoration rate of sinus rhythm.¹⁴ Studies in pediatric patients have shown an 81% successful conversion rate of primarily atrial reentrant tachycardia without significant complications.¹⁵ Indications for transesophageal pacing include decompensated sinus bradycardia, contraindications to or ineffective pharmacologic resuscitation, transcutaneous pacing failing to capture, and unavailable or delayed transvenous pacing.^{16,17}

Transesophageal pacing is used more frequently in Cardiology suites than the Emergency Department. It is used for diagnosis of complex supraventricular arrhythmias with amplified P waves, echocardiography, and nonexercise stress testing. It is used for overdrive pacing of atrial flutter and other supraventricular tachycardias. Cardiologists induce atrial arrhythmias to determine effectiveness of therapy. They temporarily pace bradycardia, hypotension, and sick sinus syndrome. Transesophageal pacing is used temporarily in pediatrics. It is also used to determine abnormal left atrial activity during ablations.

CONTRAINDICATIONS

No absolute contraindication to transesophageal atrial pacing exists in the unstable or symptomatic patient with an intact esophagus. **It is not a first-line means of resuscitation in the hemodynamically unstable or decompensating patient. This procedure is not intended as a life-sustaining practice and should not be used for patients with total heart block.** These individuals require timely and dependable ventricular pacing, which cannot be guaranteed with this technique. Transesophageal ventricular pacing is limited by the distance between the esophagus and heart. It requires much greater energy to achieve capture. These factors increase the risk of local tissue injury and inconsistent cardiac pacing during an emergent or resuscitative event.

Assess the patient for historical or physical features that could make the passage of a transesophageal probe difficult or dangerous.¹⁸ The ability to follow directions is important to safe completion of this procedure. Known anatomic variants (e.g., diverticular disease or esophageal strictures), surgical interventions, or trauma may limit the success of transesophageal pacing and necessitate an alternative means of patient stabilization or diagnosis.

EQUIPMENT

- Lidocaine (e.g., aerosolized, gel, or paste)
- 5 or 10 French bipolar or quadripolar pacing catheter or pill electrode (**Figure 44-3**)
- Cardiac monitor or ECG machine
- ECG lead wire with alligator clip
- Pulse generator or cardiac stimulator (**Figure 44-4**)
- Ultrasound (US) machine
- US gel

FIGURE 44-2. Cardioversion of atrial flutter to normal sinus rhythm. Note the transient atrial fibrillation. (Courtesy of CardioCommand Inc., Tampa, FL.)

- US transducer, 6 to 12 MHz, high-frequency
- US transducer, curvilinear or microconvex in obese patients

Transesophageal atrial pacing is often accomplished through one of two pacing devices. First is a pill electrode secured to a flexible wire and swallowed by the patient.¹⁹ This is rarely available in the Emergency Department. Second is a flexible catheter that may be inserted via the nares or mouth into the esophagus (**Figure 44-3**).¹⁹ Use bipolar or quadripolar devices as they are readily available and successful at safely obtaining atrial capture. A pulse generator or commercially available cardiac stimulator as typically used in electrophysiology is used for atrial pacing (**Figure 44-4**).^{18,20} Certain unique aspects of transesophageal pacing make the use of external

FIGURE 44-3. The tips of the esophageal pacing electrode. **A.** Tapcath 205 (CardioCommand Inc., Tampa, FL). **B.** Ecosoft S. (Courtesy of FIAB, Firenze, Italy.)

FIGURE 44-4. Esophageal cardiac pacemakers. **A.** The Model 7A Stimulator and the Model 3 Pre-amplifier. (Courtesy of CardioCommand Inc., Tampa, FL.) **B.** The Asynchronous Esophageal Cardiac Pacer 2007. (Courtesy of FIAB, Firenze, Italy.)

pacing generators ineffective and necessitate a dedicated transesophageal pacer.

Many hospitals use the CardioCommand devices (CardioCommand Inc., Tampa, FL) (**Figure 44-4A**). The Model 7A stimulator was designed for transesophageal pacing. It has dedicated controls and sets up quickly. It can regulate capture frequency, heart rate, pacing intensity, and pulse width. The Model 3 Amplifier links the esophageal catheter and the ECG monitor. It eliminates artifacts (e.g., due to breathing, esophageal peristalsis, and swallowing). It allows simultaneous recording of esophageal and surface ECGs. It also transmits the pacing impulses from the stimulator to the esophageal catheter.

Equipment for successful transesophageal atrial pacing is available in most hospitals. Commercially available prepackaged kits are useful in facilities completing frequent transesophageal pacing or serving a population that might benefit from emergent access to this procedure.

PATIENT PREPARATION

Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Discuss the patient expectations.¹⁸ Obtain an informed consent for the procedure, and place this in the medical record. When performing the procedure on a neonate or child, it is advisable to give the parent the option to leave the room or look away as the procedure can be disconcerting to some parents.

Screen patients for prior medical and surgical history that might complicate transesophageal pacing. Apply external hemodynamic monitoring (i.e., blood pressure cuff, ECG monitoring, and pulse oximetry). Provide supplemental oxygen. The use of pharmacologic adjuncts depends on route of administration and patient tolerance. Consider topical anesthesia with aerosolized lidocaine spray to desensitize the nares or oropharynx. Consider the use of anxiolysis with weight-based intravenous midazolam to promote patient tolerance of the procedure on a case-by-case basis.¹⁵ Consider procedural sedation, especially in children (Chapter 159). Consider the administration of an antiemetic. **Have airway management, a cardioverter-defibrillator unit, emergent resuscitation, and suction available and nearby.** Patient positioning is dependent on patient preference and provider comfort when the patient is awake. Patients are often seated upright to facilitate esophageal catheter passage. Frequently assess the patient for cardiac instability, discomfort, or pulmonary distress.¹⁸

TECHNIQUE

Place the transesophageal atrial electrode in accordance with patient participation and comfort. Use a swallowed tethered pill electrode for older patients or those capable of cooperating. An alternative method and the method most used in the Emergency Department is an electrode catheter inserted through the nares. Depth of insertion (DOI) guidelines are available on commercial transesophageal pacing kits based on patient height. Atrial capture is often successful at an oral DOI calculated as follows: DOI (cm) = (patient height [cm] ÷ 5); or DOI (cm) = (height [inches] ÷ 2 ± 3 cm for variability).^{20,21} Add an additional 3 to 4 cm to the calculated DOI for nasal insertion.^{20,21} Atrial capture is achieved within 36 to 37 cm as the DOI.^{22,23} An example is a 6 foot tall individual measuring 183 cm tall. The insertion depth is 36.6 cm ± 3 cm for oropharyngeal insertion or 40 cm ± 3 cm for nasal placement.

Insert the esophageal pacing catheter like a nasogastric tube (Chapter 75). Attach the alligator clip to the negative terminal of the esophageal pacing catheter and the other side to lead V₁ of the ECG monitor. Turn on the ECG monitor set to lead V₁. Insert the pacing catheter to an initial DOI of [(height {cm} ÷ 5) + 5] orally or

FIGURE 44-5. The optimal positioning of the esophageal electrode and its impact on atrial depolarization amplitude. (Courtesy of CardioCommand Inc., Tampa, FL.)

[(height {cm} ÷ 5) + 9] nasally. Withdraw the pacing catheter while watching the ECG until the point of maximal esophagoatrial ECG deflection, which closely approximates the point of minimum atrial pacing threshold (**Figure 44-5**).²⁴

Identifying the minimal atrial threshold will help improve patient comfort and limit the potentially harmful use of excessive amperage during this procedure.^{1,21} Lowest stimulatory thresholds are often captured with atrial pulse widths of approximately 10 milliseconds.^{22,25} Adjust the electrical current to produce consistent and reliable atrial pacing. This often occurs between 5 and 25 milliamperes.²⁶ A dedicated pacing device is required to safely complete this procedure rather than those typically used for endocardial or transthoracic pacing (**Figure 44-4**).²⁷ This is due to the unique strength duration curve associated with esophageal pacing.

ALTERNATIVE TECHNIQUES

The technique of transesophageal pacer placement and initiation has limited variability. Confirmation of placement may be aided by US. The utility of US in confirming the placement of nasogastric tubes is well known and could theoretically be applied to transesophageal pacing.²⁸ Evaluate the anterior neck with US. Assess the location, orientation, and contour of the esophagus for any variation.

Placement of a transesophageal pacing catheter may be confirmed in real time during the advancement of the device or afterward. Prepare the US transducer. Have an assistant apply US gel over the footprint of the transducer. Place the transducer on the anterior neck with the marker facing the patient's right. A hyperechoic structure in the esophagus corresponds with the catheter.²⁹ Advance the device to the predetermined depth. The catheter can be removed and advancement reattempted depending on clinical circumstances and patient tolerance if concerned about incorrect placement.

Little is known about the use of US for confirming placement of pacing pill electrodes. The likelihood of incorrect positioning is presumed to be low given the necessity of patient participation in swallowing the device unless underlying structural variation or

dysphagia is present. The tethering wire or electrode may be seen in the esophagus depending on echogenicity or depth. Further investigation on this topic may be warranted.

PEDIATRIC CONSIDERATIONS

Transesophageal pacing is most frequently cited in pediatric cases of atrial or supraventricular dysrhythmias. No specific changes or alterations to this technique are required for children.^{13,30} Use appropriately sized catheters. Use a 6 French pacing catheter for neonates or children up to 15 kg and a 7 French pacing catheter for larger children.³¹ Adjust medication doses according to patient weight and medical comorbidities.

ASSESSMENT

Assess the patient for electrical and mechanical capture after placement of the transesophageal pacing catheter. Successful electrical capture is demonstrated by a prominent P-wave deflection on the ECG with restoration of a regular rhythm at the paced rate. Address failure to capture by ensuring optimal catheter placement and adjusting pacer depth.³

Confirm mechanical capture through physical examination and hemodynamic monitoring. A palpable pulse matching the paced rate will correspond to the cardiac monitor. Intraarterial blood pressure monitoring is a suitable alternative to pulse palpation. Absence of a pulse at the paced rate represents a failure of mechanical capture. Increase the pacing current until capture is confirmed.^{3,21}

AFTERCARE

Secure the pacing catheter following successful transesophageal pacing and confirmation of the point of maximal ECG deflection. Tape the catheter to the patient's nose or cheek, similar to a nasogastric or orogastric tube (Chapter 75). Apply additional catheter securing devices or restrain the patient if they are considered a high risk for accidental catheter removal.¹⁸

Regularly assess the patient for electrical and mechanical capture. Ensure continuous ECG monitoring, frequent pulse palpation, and frequent blood pressure checks for patient safety and to rapidly identify any changes in transesophageal pacing. **This technique is intended for short-term or temporizing use, and invasive hemodynamic monitoring is not warranted unless indicated for another reason.**

Make patient comfort a priority throughout this procedure. Provide deescalation and verbal reassurance for the management of agitation or anxiety. Redosing of anxiolysis or pain control medications may be needed throughout the procedure to decrease discomfort.

Remove the pacing catheter or pill electrode in patients no longer requiring transesophageal pacing. Assess the patient for possible trauma sustained during placement or maintenance of the device. Complete a challenge of oral intake when appropriate.¹⁸ Local irritation and discomfort are possible. Oral intolerance or progressive pain following intake should prompt further imaging or investigation for esophageal injury.³²

COMPLICATIONS

Complications related to transesophageal atrial pacing are rare. The complications associated with nasogastric insertion are discussed in detail in Chapter 75. This minimally invasive procedure is well tolerated by patients. There has been no reported mortality or long-term morbidity throughout its worldwide use as a diagnostic and therapeutic tool. Nonsustained ventricular fibrillation and ventricular tachycardia have been rarely reported in infants with

Wolf-Parkinson-White syndrome.¹ The means to emergently stabilize and cardiovert/defibrillate patients should be readily available.

The transesophageal pacer is used for a limited time. Esophageal irritation is a possible complication of prolonged transesophageal pacing, as evidenced by a mild esophageal ulceration discovered during autopsy of an adult undergoing 60 hours of continuous pacing.¹ There are no documented cases of esophageal perforation or long-term dysfunction associated with this procedure. Accidental placement in the trachea could result in patient injury or respiratory distress.

Consider patient comfort, participatory ability, and aspiration risks. These are minimized by adequate anesthesia and careful explanation of the procedure. Patient discomfort may limit the initiation or completion of transesophageal pacing. **Airway protection is vital throughout this procedure.** Assess the patient for aspiration risk. Include the time of last oral intake, known medical comorbidities, and prior adverse responses to procedures. **Tools necessary for emergent airway management should be available during transesophageal pacing.**

SUMMARY

Transesophageal pacing has been clinically implemented since the late 1950s for the diagnosis and management of supraventricular dysrhythmias and symptomatic bradycardia. Extremely limited literature exists to support its regular use. This procedure may be initiated within minutes following very little patient preparation. Transesophageal pacing has demonstrated great success for temporary stabilization and conversion of certain abnormal cardiac rhythms, especially in pediatric populations. Transesophageal pacing may be initiated if transcutaneous or transvenous pacing is not readily available or clinical circumstances do not support these techniques. This technique is not intended for use during asystole and has not been validated for the management of drug-induced bradycardia.

Pacemaker Assessment

Elizabeth Kwan

INTRODUCTION

Cardiac rhythm management devices (CRMDs) are becoming increasingly common as our population ages and indications for their use broaden.¹ These devices are becoming increasingly complex. Single-chamber devices with only a pacing function have given way to dual-chamber devices with the ability to sense and programmable features (e.g., automatic mode switching or rate

responsiveness). Implantable cardioverter-defibrillators (ICD) have been developed as primary and secondary prevention for sudden cardiac death and have a backup pacemaker function. **Biventricular pacemakers are known as cardiac resynchronization therapy (CRT). They were developed to coordinate the action of the right and left ventricles for patients with reduced systolic function and delayed conduction defined by a wide QRS.** Most CRT devices have an associated defibrillator (CRT-D) since indications for CRT are associated with a high risk for ventricular tachycardia (VT) and ventricular fibrillation (VF).

Have a very low threshold for formal device interrogation and Cardiologist consultation when a malfunction is suspected given the complexity of the current generation of pacemakers. **The Emergency Physician must be careful not to prematurely attribute a patient's presentation to a pacemaker malfunction.** Consider life-threatening and other conditions while awaiting pacemaker interrogation. Any critical illness causing severe metabolic derangements (e.g., acidosis, hypoxemia, or hyperkalemia) can interfere with device function by altering the tissue interface with the myocardium.

Pacemakers have become more complex. They are more reliable with better hermetic sealing, better batteries and circuitry, the use of bipolar instead of unipolar leads, and special programming to prevent rhythm-related complications. **Pseudo-malfunctions occur when a device is functioning as programmed but there are unexpected or unusual electrocardiogram (ECG) findings. The pseudo-malfunction is more common than a true malfunction.**

It may not be obvious when a patient presents to the Emergency Department if their symptoms are due to a pacemaker malfunction. The patient may not even provide a history of having pacemaker. The goal of this chapter is to prepare the Emergency Physician to manage patients presenting with symptoms that may be related to these devices and to understand how the presence of a pacemaker may affect patient care. The common term *pacemaker spike* is used instead of *pacemaker artifact* throughout this chapter.

INDICATIONS FOR PACEMAKER PLACEMENT

Consensus guidelines for pacemaker placement have been established by the American College of Cardiology (ACC), the American Heart Association (AHA), and the Heart Rhythm Society (HRS).² Pacemakers are placed most often for symptomatic bradycardia from sinus node dysfunction or atrioventricular block (**Figures 45-1 and 45-2**). CRT pacemakers are placed for advanced heart failure with conduction delays as defined by a wide QRS interval. CRT improves cardiac function, quality of life, and survival.³ Placement of ICDs is for primary and secondary prevention of VT or VF. ICD patients often overlap with patients needing CRT, with most CRT devices having a defibrillator, known as CRT-D.⁴

PACEMAKER PARTS AND FUNCTION

The pacemaker has the functions of creating electrical impulses to pace the myocardium, sensing the heart's intrinsic electrical activity, and responding by pacing or inhibiting pacing. It stores diagnostic information. **The pacemaker can inhibit itself but cannot inhibit the heart.** It may incidentally suppress intrinsic activity because paced depolarizations will make the myocardium refractory to native impulses. All references to pacemaker inhibition refer to inhibition of its own pacing activity. **A function of newer pacemakers is rate responsiveness. This allows for increased physical activity by increasing the paced rate in response to increased metabolic demands.**

Pacemakers consist of a pulse generator connected to a lead or leads. The generator has a battery and circuitry that interprets

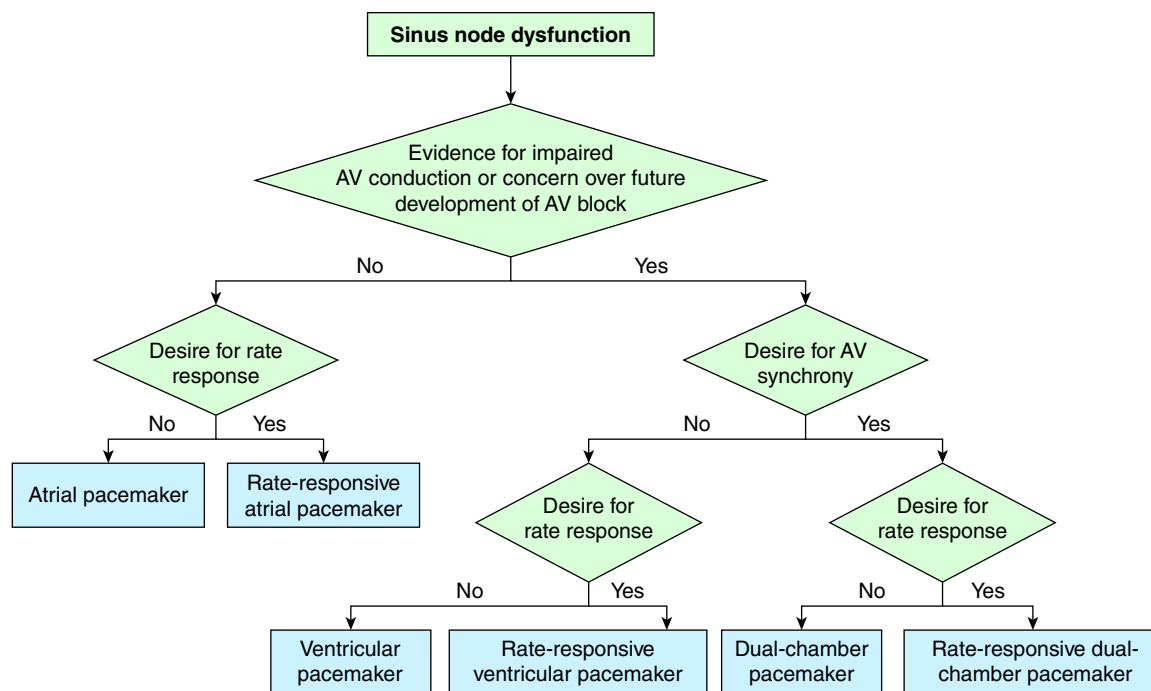

FIGURE 45-1. Selection of pacemaker systems for patients with sinus node dysfunction. Decisions are illustrated by diamonds. Shaded boxes indicate type of pacemaker. AV, atrioventricular. (Used with permission from reference 2.)

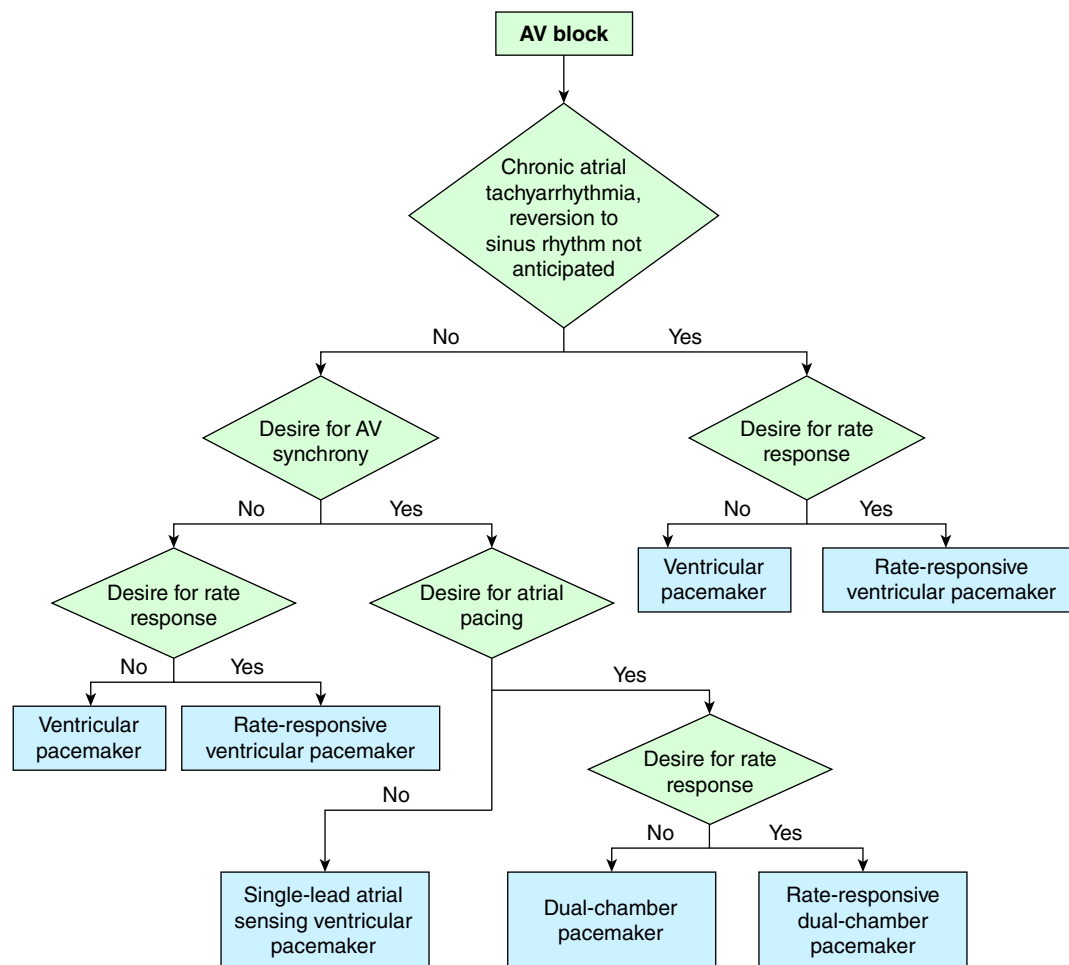

FIGURE 45-2. Selection of pacemaker systems for patients with atrioventricular (AV) block. Decisions are illustrated by diamonds. Shaded boxes indicate type of pacemaker. (Used with permission from reference 1.)

sensor information and creates pacing stimuli. The generator is usually placed in a subcutaneous pocket in the upper anterior chest. The leads are wires connected to the pacing generator and deliver the electrical impulses from the generator, detect the intrinsic electrical activity of the native heart, and deliver those signals back to the generator.

Unipolar leads leave a bigger spike on the ECG and are less common than bipolar leads. The negative electrode of unipolar leads is at the end of the wire, and the metal generator casing acts as the positive electrode. The current to pace or to sense must travel through all the tissue between them to complete the circuit.

Bipolar leads contain two layers of insulated wires. The negative electrode is at the tip of the lead. The positive electrode forms a ring just proximal to the tip of the lead. **The current flows in a much smaller area in the bipolar lead because the electrodes are close together.** This may result in bipolar pacing spikes not visible on the ECG. Bipolar leads are much less likely to stimulate other body tissues or to oversense and mistake electrical activity outside the heart as cardiac impulses.

Leads are usually placed into the subclavian vein and fluoroscopically guided into position in the heart. They may be fixed passively into the trabeculae of the myocardial wall or fixed using screws. Leads are right sided in dual-chamber pacemakers and endocardial (i.e., placed on the inner surface of the heart). The atrial lead is in the right atrial appendage. The right ventricular (RV) lead can be at the apex, RV outflow tract, or the interventricular septum. CRT is biventricular pacing with a third lead to the left ventricle (LV) to allow the simultaneous pacing of the RV and LV. The LV lead passes through the coronary sinus, passes through the myocardium via veins to the epicardium (i.e., outer surface of the heart), and passes along the posterior or lateral free wall of the LV.

Pacemakers work by forming a closed circuit that includes the pacemaker and the myocardial tissue to carry out its pacing and sensing functions. The battery stores the voltage, which is the potential to move electrons. Leads deliver electrons as current. The current in this closed circuit moves from the battery, through the leads, from the negative electrode across the myocardial tissue, and then back to the positive electrode. **The circuit must be a closed loop for any movement of current.** Additional circuitry within the generator carries out programming.

PACEMAKER MODES

The North American Society for Pacing and Electrophysiology and the British Pacing and Electrophysiology Group use a universal five-letter pacemaker code (Table 45-1). The combination of these letters describes the pacemaker mode or function. The code does not describe the characteristics, specific functions, or unique functions that are specific to each pacemaker or its manufacturer. The character position is labeled in Roman numerals I through V. The first three letters are most commonly used.

The first letter designates the chamber(s) in which pacing occurs. It can be designated as atrial (A), ventricular (V), both atrial and ventricular (D or dual), or none (O). The second letter designates the chamber(s) used by the pacemaker to sense intrinsic electrical cardiac activity. It can be designated as atrial (A), ventricular (V), both atrial and ventricular (D or dual), or none (O). The third letter designates how the pacemaker responds to sensed intrinsic electrical activity. A sensed event may inhibit the pacemaker (I), trigger the pacemaker (T), both inhibit and trigger the pacemaker (D), or cause no response (O) from the pacemaker generator.

How would an emergent transvenous pacemaker with a single lead in the RV be described? When first being placed in asynchronous mode, it would be VOO: paces the ventricle (V–), with no sensing (VO–) and no response to sensing (VOO). It changes to VVI once set for sensing. It paces in the ventricle (V–), is sensed in the ventricle (VV–), and is inhibited when intrinsic electrical activity is sensed (VVI).

DDD pacemakers represented 82% of new implantations in 2009, compared to single-chamber VVI or AAI pacemakers, which accounted for 14% and 1%, respectively.⁵ Patients with sinus dysfunction but intact atrioventricular (AV) conduction may only need AAI pacing. They often get a dual-chamber pacemaker because there is the risk of developing an AV conduction problem and replacing the device and leads is not without risk. Biventricular CRT devices represented 4% of new implantations in 2009, but represented 10% of cardiac rhythm management devices placed from 2007 to 2013 in another study.⁴ CRT devices may continue to grow as a proportion of CRMD as more studies support expanding indications for CRT and deleterious effects on LV function from long-term pacing of a RV lead, particularly in patients with preexisting LV dysfunction.

The fourth and fifth letters are rarely used, as these functions are not often used. The fourth letter refers to whether the pacemaker is rate responsive (R) or if this feature is absent or turned off (O). Rate-responsive pacemakers estimate metabolic demands by using an accelerometer to detect motion and using changes in chest wall impedance as a measure of minute ventilation. It interprets an increase in motion or minute ventilation as increased activity and increases the pacemaker rate to accommodate exercise. This is an important feature for active patients. Rate responsiveness is turned off when a magnet is placed over the device and the pacemaker is made asynchronous.^{6,7} The fifth letter designates antitachyarrhythmic function.

PACEMAKER TIMING INTERVALS

Pacemakers have multiple programmable intervals to determine when to deliver a pacing output. It is important to understand basic pacemaker timing intervals to understand pacemaker function and safety features. The pacemaker timing cycle starts DDD pacemakers with either an intrinsic or paced atrial depolarization (Figure 45-3). This starts the atrial ventricular interval (AVI), the time from atrial

TABLE 45-1 The Generic and Standard Pacemaker Codes

Position	I	II	III	IV	V
Interpretation	Chamber(s) paced	Chamber(s) sensed	Response to sensing	Programmability rate modulation	Antitachyarrhythmia function(s)

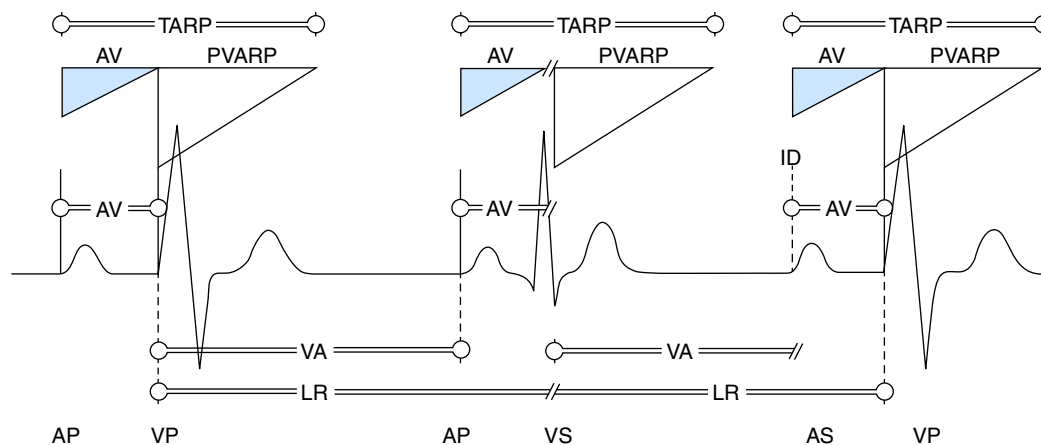

FIGURE 45-3. Dual-chamber pacemaker timing cycles. The timing cycle in DDD consists of a lower rate (LR) limit, an atrioventricular (AV) interval, a ventricular refractory period, a postventricular atrial refractory period (PVARP), and an upper rate limit. If intrinsic atrial and ventricular activity occur before the LR limit times out, both channels are inhibited and no pacing occurs. In the absence of intrinsic atrial and ventricular activity, AV sequential pacing occurs (first cycle). If no atrial activity is sensed before the ventriculoatrial (VA) interval is completed, an atrial pacing artifact is delivered, which initiates the AV interval. If intrinsic ventricular activity occurs before the termination of the AV interval, the ventricular output from the pacemaker is inhibited (i.e., atrial pacing with intrinsic conduction [second cycle]). If a P wave is sensed before the VA interval is completed, output from the atrial channel is inhibited. The AV interval is initiated, and if no ventricular activity is sensed before the AV interval terminates, a ventricular pacing artifact is delivered (i.e., P-synchronous ventricular pacing [third cycle]). AP, atrial pace; AS, atrial-sensed event; ID, intrinsic deflection; TARP, total atrial refractory period; VP, ventricular pace; VS, ventricular event. (Used with permission from reference 7.)

to ventricular depolarization, which is analogous to the PR interval. A paced QRS is triggered if there is no intrinsic QRS by the end of a programmed AV delay. The AV delay is analogous to the longest PR interval the pacemaker will tolerate. If an intrinsic QRS occurs within the programmed AV delay, there will be no ventricular pacing artifact on the surface ECG and the AVI will be shorter than the programmed AV delay. The QRS starts the ventricular-atrial interval, the time from ventricular to atrial depolarization. This is also known as the atrial escape interval (AEI), or the programmed amount of time the pacemaker will wait for an intrinsic P wave to “escape” before pacing the atrium.⁸

Immediately after ventricular depolarization the postventricular atrial refractory period (PVARP) begins. The AVI and PVARP make up the total atrial refractory period (TARP). The atrial lead is refractory during the TARP and will not deliver a pacing impulse. The TARP determines the pacemaker’s upper rate limit or the minimum amount of time before the next atrial impulse can be delivered to start the next AVI and trigger a paced ventricular depolarization. The lower rate limit is defined by the programmed intervals that define the maximum time in the cycle that the pacemaker will wait for intrinsic depolarization (i.e., the AV delay plus the AEI). The pacemaker will trigger an atrial paced beat to restart the AVI if no intrinsic P wave occurs by the end of the AEI. The pacemaker will sense and record the impulse in the refractory period but will not alter the timing cycle.⁸

There is a brief blanking period in all chambers in addition to the refractory period immediately after each pacing stimulus during which the pacer will not sense. This is meant to prevent “cross-talk” when a pacing stimulus in one chamber is interpreted as a depolarization in the other. If an atrial pacing stimulus starts being interpreted as an intrinsic ventricular signal, ventricular pacing will be inappropriately inhibited indefinitely and lead to asystole.⁸

COMMON SAFETY FEATURES

Ventricular safety pacing is a protection against cross-talk and precipitating ventricular tachyarrhythmias by pacing early before the vulnerable part of the T wave. There is a cross-talk sensing window after the brief blanking period. The pacemaker delivers a ventricular pacer spike early if any ventricular activity is detected during this

period. Ventricular safety pacing prevents asystole if the ventricular signal detected was cross-talk (i.e., a misinterpreted atrial pacing event). The early ventricular pacer spike prevents pacing during the vulnerable part of the T wave that could precipitate ventricular arrhythmias if the ventricular signal in the cross-talk window was a premature ventricular contraction (PVC). The myocardium would be refractory from the PVC, and there is no additional QRS. Suspect ventricular safety pacing on the ECG when a ventricular pacer spike occurs soon after an atrial pacer spike or a PVC that lands when an atrial pacer spike is expected.⁹

MINIMIZING RIGHT VENTRICULAR PACING

RV pacing contracts the myocardium starting in RV and then spreads to the septum and then the LV. It simulates a left bundle branch block (LBBB) on the ECG. This altered conduction causes adverse remodeling, altered LV perfusion, and dyssynchrony.^{10,11} Pacing that maintains AV synchrony (e.g., DDD with intact sinus node function or AAI with intact AV conduction) has additional advantages. Atrial or dual-chamber pacing reduces the incidence of atrial fibrillation from 22% to 17% and decreases the risk of stroke.¹² Keeping AV synchrony results in a better ejection fraction than ventricular pacing by preserving “atrial kick.” It reduces the risk of the pacemaker syndrome ranging from discomfort to overt heart failure resulting from AV asynchrony.

The degree of adverse effects of RV pacing may be related to its frequency and duration.¹² Advances in pacemaker technology allow minimizing RV pacing when possible through automatic mode switching and allows slow native rates. These measures preserve AV synchrony, minimizing the long-term harm to LV function, and minimizing battery usage.

AUTOMATIC MODE SWITCH

Automatic mode switching allows a pacemaker to function as AAI with a backup DDD function if absent AV conduction is detected. The pacemaker will periodically revert to AAI pacing to assess intrinsic AV conduction.¹³ **Mode switching protects against fast atrial rates.** The pacemaker can switch from a DDD mode if an atrial tachycardia is detected to DDI, DVI, or VVI to stop the triggering of ventricular pacing by atrial impulses. The pacemaker

will go back to DDD mode when the intrinsic atrial rate falls below a programmed threshold.¹²

HYSTERESIS, REST, AND SLEEP MODES

The heart rate naturally slows during sleep to meet the lower physiologic demands. Pacemakers have modes to mimic this phenomenon and allow rates slower than the preprogrammed lower rate limit. The heart benefits from the decreased heart rate during sleep. Experimental data on patients with DDD pacemakers show that systolic and diastolic function decline without this rest.¹⁴

Manufacturers use different approaches. St. Jude offers a “rest mode” of 10 to 20 beats a minute less than the lower rate limit if patient activity decreases below a preset threshold for 15 to 20 minutes. This is measured with the same accelerometer as the rate response feature. Medtronic “sleep mode” decreases the paced rate during specific hours of the day. Rest and sleep modes do not rely on sensing the intrinsic rhythm and will not be turned off by magnet application.¹⁵ Boston Scientific pacemakers have a hysteresis function, derived from the Greek word for “late.” The pacemaker may have a programmed lower rate limit of 60 beats per minute when pacing and a hysteresis rate of 50 beats per minute. The pacemaker will allow the intrinsic rate to fall as low as 50 beats per minute before it starts pacing at a rate of 60 beats per minute. This feature relies on sensing the intrinsic rate. Turning off sensing with the application of a magnet turns off hysteresis.¹⁵

DIFFERENTIAL DIAGNOSIS OF POTENTIAL PACEMAKER MALFUNCTION BASED ON ECG FINDINGS

CATEGORIZING PACEMAKER MALFUNCTION

The conventional categories of pacemaker malfunction are based on electrophysiologic mechanisms. These categories are more useful to someone programming a pacemaker than the Emergency Physician managing a patient with limited information. **Failure to pace is noted by a lack of the pacemaker spike on the ECG and the failure to deliver a stimulus to the myocardium when there is a pause in the intrinsic cardiac electrical activity. Failure to sense is a result of the inability of the pacemaker to sense the native cardiac activity. It is recognized by noting pacemaker spikes on the ECG despite the patient’s intrinsic cardiac rate being higher than the pacemaker’s programmed rate. Failure to capture is detected by the lack of a QRS complex (i.e., myocardial depolarization) or a lack of a QRS complex after an appropriately timed and placed pacemaker spike on the ECG (Figure 35-3).** Failure to pace, sense, and capture are precipitated by changes in the circuit formed by the pacemaker and the myocardium.

Problems can arise at any part of the circuit. The battery can be depleted. Circuitry within the generator can be damaged. Leads can fracture, get disconnected from the generator, or dislodge from the myocardium. Lead insulation can break. The myocardium completes the circuit, and changes (e.g., fibrosis, inflammation, ischemia, or metabolic changes) can affect pacemaker function. **Problems at the myocardial interface are numerous, common, and time sensitive. Hyperkalemia, ischemia, hypoxia, hypercarbia, or many other metabolic derangements can alter the pacing threshold or change the intrinsic electrical activity sensed (Table 45-2).** Malfunctions can arise from the damage or failure of the circuitry within the generator that carries out the programming.

Given the complexity of pacemaker programming and safety features, an approach that considers both malfunctions and pseudo-malfunctions may be more useful to the Emergency Physician.

TABLE 45-2 Factors That Can Change Pacemaker Capture Thresholds¹⁸

Metabolic factors that increase the capture threshold

Acidosis
Alkalosis
Hypercarbia
Hyperkalemia
Hypoxemia
Myxedema
Severe hyperglycemia

Medications that increase the pacing threshold

Dofetilide (class III antiarrhythmic)
Flecainide (class IC antiarrhythmic)
Mineralocorticoids
Propafenone (class IC antiarrhythmic)
Sotalol (class III antiarrhythmic)

Medications that possibly increase the pacing threshold

Beta-adrenergic blockers (class II antiarrhythmic)
Ibutilide (class III antiarrhythmic)
Lidocaine (class IB antiarrhythmic)
Procainamide (class IA antiarrhythmic)
Quinidine (class IA antiarrhythmic)

Medications that decrease the pacing threshold

Atropine
Epinephrine
Glucocorticoids
Isoproterenol

Figure 45-4 summarizes the differential diagnosis of the potential pacemaker malfunctions based on the ECG appearance.

FAILURE TO CAPTURE

Failure to capture is detected by the lack of a QRS complex or lack of a QRS complex after an appropriately timed and placed pacemaker spike on the ECG (Figure 35-5). It occurs when the generated pacing impulse is incapable of effectively depolarizing the myocardium. This can be due to inadequate output delivered to the myocardium or to an increased threshold required due to conditions at the tissue interface. Lack of capture or intermittent capture could be a result of the inadequate energy generation by the pacemaker (i.e., battery failure), increased resistance at the electrode-myocardium interface (i.e., lead fracture or displacement), poor electrode positioning, prolongation of the refractory state of the myocardium (e.g., myocardial infarction, electrolyte abnormalities, supratherapeutic levels of antidysrhythmic drugs), or perforation of the myocardium by the electrode (Table 45-2).¹⁶ **Hyperkalemia and ischemia are common and immediately life-threatening causes of increased capture threshold.** Isoproterenol has been shown to be an effective therapy for patients with failure to capture from high antidysrhythmic drug levels.^{16,17} Fibrosis and inflammation at the tissue interface in the weeks following implantation or from cardiomyopathies can increase the capture threshold. Any critically ill patient with a pacemaker may develop failure to capture.

Failure to capture during the postimplantation period could result from an elevated voltage threshold for pacing due to tissue changes at the electrode-myocardium interface.^{16,17} The occurrence of postimplantation failure to capture typically occurs in the first few weeks after implantation. Its incidence has decreased because of recent advances in steroid-eluting leads.^{16,17}

A poor threshold may be present from the time of implantation. A chronic rise in threshold can be related to fibrosis around the tip of the lead causing lack of capture or intermittent capture. Severe metabolic abnormalities and drugs can increase the pacing

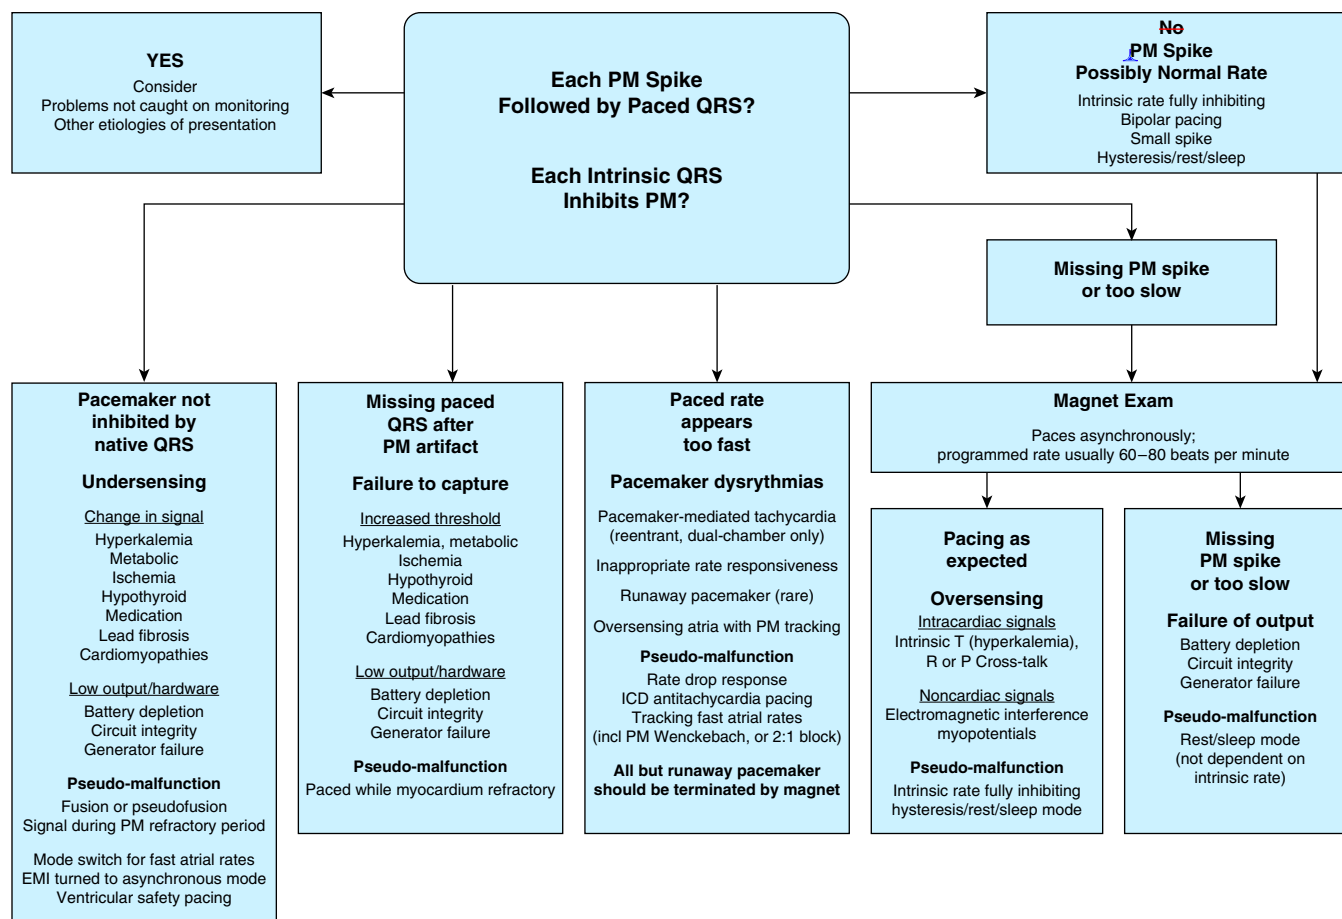

FIGURE 45-4. Differential diagnosis of pacemaker malfunction (PM). EMI, electromagnetic interference.

threshold. A myocardial infarction involving the myocardium at the tip of the pacer leads will cause a rise in the pacing threshold. Lead fracture and poor connections between the electrode and generator can present as lack of capture or intermittent capture. The pacemaker generator battery may fail and present with too low a voltage to capture the heart but enough voltage to generate a pacemaker spike. Insulation breaks in the pacemaker lead allow parallel electrical circuits to occur in the system and may cause various pacemaker abnormalities.

FAILURE TO PACE

Failure to pace is a result of either pacemaker output failure (lack of a pacer spike) or failure to capture (lack of a myocardium stimulation after a pacer spike). Failure to pace is noted by a lack of the pacemaker spike on the ECG and the failure to deliver a stimulus to the myocardium when there is a pause in the intrinsic cardiac electrical activity. **The pacer-dependent patient may complain of chest pain, dizziness, lightheadedness, weakness, near-syncope, syncope, or other signs of hypoperfusion.**

Failure to pace can be intermittent or continuous, cause long pauses on telemetry, or show a rate slower than the programmed minimum rate. This can be life threatening for a pacemaker-dependent patient. Be prepared to use transcutaneous pacing (Chapter 41) or to place a transvenous pacemaker (Chapter 43) for potentially unstable patients.

FAILURE TO PACE DUE TO OVERSENSING

Oversensing is the inappropriate inhibition of the pacemaker due to its sensing of signals that it should otherwise ignore. The most common reason for failure to pace is oversensing. The pacemaker is inappropriately inhibited. Oversensing may be due to intracardiac signals (e.g., P waves, R waves, or T waves) or noncardiac signals (e.g., myopotentials from the chest wall). T waves may be sensed inappropriately (e.g., hyperkalemia, LV hypertrophy, and severe hyperglycemia).⁹ The R wave may be sensed as an intrinsic atrial signal. This is reflected on the ECG as a slow rate or a prolongation of the pacing spike interval (Figure 45-6). Ventricular oversensing is associated with slow heart rates since the pacemaker is

FIGURE 45-5. ECG monitor strip of an AV sequential pacemaker demonstrating lack of capture or intermittent capture.

FIGURE 45-6. ECG monitor strip demonstrating oversensing.

inhibited by intrinsic signals. Atrial oversensing may cause fast rates if the pacemaker is tracking misinterpreted signals that are fast. The patient may develop symptoms from loss of AV synchrony if the pacemaker stops tracking these signals by automatic mode switch from DDD to VVI.

Cross-talk when a paced event from one chamber is mistakenly interpreted as activity in the other chamber is a form of intracardiac oversensing. Brief blanking periods immediately after pacing during which no sensing occurs are meant to prevent cross-talk. Ventricular safety pacing within a programmed cross-talk window following the blanking period is additional protection against asystole when there is cross-talk. Noncardiac signals may be sensed (e.g., electromagnetic interference [EMI] and myopotentials from the chest wall or diaphragm).

EMI can cause intermittent oversensing. Pacemakers may be programmed to turn to VVI or VOO as safety features when there is ongoing EMI. This mode switch prevents inappropriate inhibition, resulting in long pauses or asystole. EMI is unlikely to affect CRMD outside of the medical environment.^{18,19} Nonmedical sources of EMI include airport metal detectors, cellular phones, cosmetic lasers, and retail antitheft sensors. It is recommended to avoid keeping a cellular phone over the CRMD pocket and to avoid lingering near antitheft sensors in stores. Hospital sources of EMI include cardioversion, defibrillation, dental composite curing, electrocautery, ionizing radiation, magnetic resonance imaging (MRI) machines, and radiofrequency ablation.²⁰ The battery-powered single-use cautery devices used in the Emergency Department are unlikely to cause CRMD malfunction.²⁰

Oversensing has decreased in prevalence due to the use of bipolar pacing devices.²¹ Oversensing can be detected by placing a magnet over the pacemaker. The pacemaker will fire at the programmed rate if it is working properly. This indicates that the failure to pace the myocardium in a patient with bradycardia is due to oversensing. The unit may be sensing a large T wave as a QRS complex. Alternatively, it may be sensing a normal T wave as a QRS complex if the

QRS complexes are small in amplitude. Tape the magnet in place over the pacemaker generator if a patient's bradycardia is corrected. The magnet may not be directly over the pacemaker generator if the generator is pacing intermittently. Reposition the magnet and observe the results. A component of the system (i.e., generator, battery, or leads) has failed if no pacemaker spikes are seen on the ECG. The battery may be depleted or the set rate has been changed if the pacemaker spikes occur at less than the programmed rate.

FAILURE TO PACE DUE TO FAILURE OF OUTPUT

Failure of output can originate from problems in any component of the pacemaker hardware or discontinuity of the circuit (**Figure 45-7**). The closed circuit must be intact for current to be delivered. Failure to pace can result from the lead being disconnected from the generator or dislodged from the myocardium, fractured leads, or insulation failure. Batteries commonly used in pacemakers can last 5 to 10 years depending on proportion of time paced, impedance from leads and the tissue interface, and the programmed output. Pacemakers are programmed to show elective replacement indicators of battery depletion, which vary by manufacturer. Many indicators begin notifications when they have 3 months of remaining life. The indicator may be an incremental slowing of the rate or a lower paced rate on the magnet examination, which puts the pacemaker in asynchronous mode. The pacemaker behavior and its behavior in magnet mode can be unpredictable at the end of battery life.¹⁸ Battery depletion can cause failure to pace, failure to sense, or failure to capture.

The incorrect diagnosis of a failure to pace and a lack of pacemaker output can be made if the patient's pacemaker spike is very small. The evaluation of multiple leads of the ECG tracing usually prevents this misdiagnosis.

A magnet exam distinguishes oversensing from failure of output in the setting of a missing pacemaker spike or an inappropriately slow rate. The magnet flips a reed switch that turns off sensing and initiates pacing at a programmed rate, usually at a rate of

FIGURE 45-7. ECG monitor strip demonstrating failure to pace from output failure.

60 to 80 beats per minute in DOO or VOO mode. The magnet will restore pacing when failure to pace is from oversensing.

The magnet can be taped in place over the pacemaker generator until the pacemaker can be reprogrammed. Make sure the magnet is directly over the pacemaker generator if pacing is intermittent. Two magnets may be needed if the patient is obese or the generator is behind the pectoral muscle. A component of the system (i.e., battery, generator, or leads) has failed if no pacemaker spikes are seen on the ECG. The battery may be depleted or the set rate has been changed if the pacemaker spikes occur at less than the programmed rate.

FAILURE TO SENSE OR UNDERSENSING

Failure to sense is a result of the inability of the pacemaker to sense the native cardiac activity. It is recognized by noting pacemaker spikes on the ECG despite the patient's intrinsic cardiac rate being higher than the pacemaker's programmed rate (Figure 45-8). The pacemaker does not sense the preceding QRS complex appropriately and fires. Patients might present with weakness, lightheadedness, and syncope due to alterations in rhythm from competition with the native cardiac rhythm. Causes of undersensing include conditions that alter the nature of cardiac signals (e.g., new bundle branch blocks, myocardial ischemia, PVCs, or premature atrial contractions). Other etiologies of failure to sense include battery failure, breaks in the lead insulation, inappropriate sensitivity programming of the pulse generator, lead dislodgement, poor electrode position, and reed switch malfunction. Many of these etiologies can result in failure to capture. Low-amplitude QRS complexes or broad QRS complexes with a low slow rate (e.g., a bundle branch block) may be responsible for pacemaker sensing problems.¹⁸

Multiple pseudo-malfunctions can appear to be undersensing. Fusion beats and pseudo-fusion beats reflect the normal delay required for sensing and inhibition (Figure 45-9). Pacing may occur immediately after an intrinsic beat that occurs within the blanking and refractory period. No sensing occurs, and intrinsic beats will be ignored during the blanking period immediately after pacing. Intrinsic signals are sensed and recorded but do not alter the timing cycle during the refractory period and do not inhibit the pacemaker. Ventricular safety pacing appears as a pacemaker spike closely following a PVC that occurs within the cross-talk window. Automatic mode switch for fast atrial rates and electromagnetic interference can cause a pacemaker to change to asynchronous pacing.

PACED RATE APPEARS FAST

Most pacemaker dysrhythmias can cause a fast rate, but most will not exceed its programmed upper rate limit or maximum tracking rate (MTR). True malfunctions include pacemaker-mediated tachycardia, inappropriate rate response, and oversensing the atria.

PACEMAKER-MEDIATED TACHYCARDIA

Pacemaker-mediated tachycardia (PMT) is a reentrant loop tachycardia in which the pacemaker fires at a high rate and is only seen

FIGURE 45-9. Schematic of typical ECG beats.

with dual-chamber pacemakers that sense the atria (Figures 45-10 and 46-4). Retrograde conduction of a PVC or a paced ventricular depolarization through the AV node causes the pacemaker to oversense the atrium, trigger another pacing stimulus in the ventricle, and form a reentrant loop. PMT will not exceed the MTR. Treatment of PMT requires interrupting the reentrant loop (Figure 46-4).

A magnet examination will terminate PMT since the reentrant loop requires sensing. This may also be accomplished by cutting the leads after they exit the generator, isometric pectoral exercises, medication that blocks the AV node (e.g., adenosine, beta-blockers, or calcium channel blockers), reprogramming, transcutaneous pacing, or a Valsalva maneuver.²² Consult a Cardiologist prior to performing any of these maneuvers. Modern pacemakers have algorithms to prevent and terminate PMT. The blanking period after a pacing event during which no sensing occurs and the cross-talk window that triggers ventricular safety pacing is meant to prevent PMT.

TRACKING ATRIAL TACHYCARDIA

The patient may present with heart rates up to the upper rate limit due exercising or tracking a supraventricular tachycardia (e.g., atrial fibrillation or oversensing atrial signals) if the pacemaker does not have an automatic mode switch to stop tracking fast atrial rates. The pacemaker will prolong the AV delay progressively to prevent pacing faster than the upper rate limit as the atrial rate exceeds the upper rate limit. The ECG will show a pacemaker Wenckebach with progressively longer PR intervals and then a 2:1 block if the rate continues to increase.⁸

INAPPROPRIATE RATE RESPONSIVENESS (SENSOR-DRIVEN TACHYCARDIA)

Rate-responsive pacemakers use an accelerometer to measure movement and chest wall electrical impedance to measure minute ventilation as an estimate of metabolic demands from exercise. The accelerometer can misinterpret movement of the generator by arm, shoulder, or muscle tremor. Interference from monitoring

FIGURE 45-8. Schematic of an ECG monitor strip demonstrating lack of appropriate sensing or failure to sense.

FIGURE 45-10. Schematic of an ECG monitor strip demonstrating pacemaker-mediated tachycardia. (Used from <https://commons.wikimedia.com>.)

equipment or hyperventilating can trigger an inappropriate rate response. Chest wall impedance is used in common cardiac monitoring equipment to measure respiratory rate and detect when the ECG leads get disconnected. The resulting tachycardia is a wide complex that is regular and may be mistaken for VT.^{23,24} Taking the patient off the monitor will restore normal pacing if the tachycardia is due to inappropriate rate response to the monitoring equipment. Rate responsiveness is turned off when a magnet is placed over the pacemaker generator. Asynchronous pacing of an intrinsic T wave can precipitate VF if the patient is in VT.^{23,24}

RATE DROP RESPONSE

Patients with recurrent vasovagal syncope may have pacemakers programmed to have a rate drop response that can be mistaken for malfunction. The pacemaker detects a sudden drop in the intrinsic rate and responds with 1 to 2 minutes of pacing at 100 to 120 beats per minute or 70% to 80% of MTR. This has been shown to reduce episodes of syncope from 1.2 to 0.3 per month.²⁵ The battery may be depleted or the set rate may have been changed if the pacemaker spikes occur at less than the programmed rate.

RUNAWAY PACEMAKER

Runaway pacemaker is an exceedingly rare pulse generator failure. Its incidence has dropped dramatically with improved batteries, improved circuitry, and improvements in hermetic sealing of the generator. Runaway pacemaker may cause dramatically rapid rates, unlike PMT, which does not exceed the programmed upper rate limit.^{16,17,26} Rates higher than 2000 beats per minute have been reported. The actual heart rate is unpredictable because pacemaker impulses from a failing generator may not all meet capture threshold to trigger ventricular depolarization. **The frequent pacing stimuli increase the risk of an R-on-T phenomenon inducing VT or VF.** Magnet application has no effect on runaway pacemaker since turning off sensing would not fix the generator's mechanical failure.^{18,27} Treatment requires emergent pacemaker reprogramming, emergent replacement, or disconnecting (i.e., cutting) the leads in the pacemaker pocket.^{9,18,26}

ANTITACHYCARDIA PACING

A pseudo-malfunction that may exceed the MTR is antitachycardia pacing (ATP) in a patient with an ICD. The ICD uses a programmed algorithm to terminate the identified dysrhythmias of VF and VT. The algorithm includes one or more trials of ATP with 6 to 10 paced impulses at a rate close to the VT rate. Using ATP will terminate VT quickly and painlessly in up to 89% of cases with VT rates of 188 to 250 beats per minute and prevents painful shocks.^{28,29}

PACEMAKER COMPLICATIONS

There are many complications associated with pacemakers and their insertion. Common complications include lead fractures, pneumothorax, pocket infections, thrombosis, and tricuspid

regurgitation (**Figure 45-11**).³⁰ They can be divided into short-term (**Figure 45-12**), intermediate-term (**Figure 45-13**), and long-term (**Figure 45-14**) complications.

ACUTE COMPLICATIONS FROM PACEMAKER INSERTION (IMPLANTATION)

Complications may occur from the implantation procedure. Discomfort and ecchymosis at the incision site or the pacemaker pocket are common in the first few days. Dehiscence of the incision can occur, especially if a large hematoma in the pocket puts excessive stress or pressure on the incision. Nonsteroidal anti-inflammatory drugs, excluding aspirin, are adequate and appropriate to alleviate the discomfort. Assure the patient that the discomfort and ecchymosis will resolve spontaneously. The patient should not be taking aspirin in the immediate postimplantation period unless authorized and/or prescribed by the Cardiologist. The pacemaker can migrate, cause pressure on the overlying skin, and result in skin erosions that require pacemaker relocation and wound debridement.

Complications from the procedure include all the complications of central venous catheterization (Chapter 63), complications from lead placement within the heart, and placement of the generator in a subcutaneous pocket.³¹ Central venous line complications include air embolism, arterial puncture, arteriovenous fistula, bleeding, brachial plexus injury, hemothorax, infection, and pneumothorax. Incision and pocket complications include ecchymosis (**Figure 45-12B**), generator migration, hematoma formation (**Figure 45-12B**), infection, and wound dehiscence. The transvenous leads are placed under fluoroscopy and affixed by screws or passively lodged into the trabecular endocardial surface. Placement may cause injury to vessels, leading to bleeding or thrombosis. Complications within the heart

include perforation and valve damage (**Figures 45-12E, 45-13C, and 45-13D**). Placement of the LV lead for biventricular pacing is technically challenging and has been associated with coronary sinus dissection.³² The leads can be misplaced (**Figures 45-12C and D**).

PACEMAKER SYNDROME

The pacemaker syndrome is caused by the adverse hemodynamic effects of AV asynchrony causing the patient to be symptomatic or limiting their ability to be fully functional. The pacemaker is usually functioning as programmed. Patients may complain of anxiety, apprehension, dizziness, dyspnea, fatigue, or neck pulsations. The Mode Selection Trial proposed the following diagnostic criteria: (1) new or worsened dyspnea, edema, elevated jugular venous pressure, orthopnea, or rales with ventriculoatrial conduction during ventricular pacing; or (2) dizziness, presyncope, syncope, or weakness with a > 20 mmHg reduction in systolic blood pressure when the patient is in VVIR pacing compared with atrial pacing or normal sinus rhythm.³³

AV asynchrony leads to decreased cardiac output and decreased LV filling. Elevated atrial pressures may initiate a vagal reflex, causing near-syncope or syncope. High wedge pressure results in shortness of breath. Patients with retrograde 1:1 ventricular to atrial conduction are more symptomatic.^{33,34} Pacemaker syndrome can occur in the absence of retrograde conduction.^{33,34} This diagnosis will not be clear from the emergency evaluation since symptoms are nonspecific and comprehensive echocardiography is not usually available around the clock. Other life-threatening causes of symptoms (e.g., ischemia or sepsis) must be evaluated. Pacemaker syndrome may resolve with a change from ventricular pacing (e.g., VVI to a mode that restores AV synchrony such as DDD). Provide supportive care until the pacemaker can be upgraded to one that

restores AV synchrony (e.g., changing a single-chamber pacemaker to a dual-chamber pacemaker).

HEMATOMAS

A hematoma may form at the site of the subcutaneous pacemaker generator (**Figure 45-12B**). This can be due to anticoagulation therapy, aspirin therapy, or an injury to a subcutaneous artery or vein. A hematoma can be managed with the application of dry, warm compresses to the area and oral analgesics. Hematomas of the pocket are usually self-limited but should be followed closely. History of a postoperative hematoma is an independent risk factor for infection.^{35,36} The Cardiologist may choose to evacuate the hematoma if it compromises the incision site. Patients taking aspirin and anticoagulants may have held the medications before the procedure, but bleeding complications may still occur. Risks and benefits of continuing these medications should be discussed between the patient and their Cardiologist. **Do not aspirate to evacuate the hematoma because it can cause further trauma, may introduce infection, or may damage the device.**²² Aspiration often does not work and does not address the etiology of the bleeding.

LEAD COMPLICATIONS

Acute presentations of pacemaker malfunction may be due to mechanical complications of leads (e.g., disconnection, dislodgment, fracture, perforation, or extracardiac pacing) (**Figure 45-14**).^{31,36} Leads can become disconnected from the generator soon after implantation. Dislodgement of leads from the myocardium often occurs within 3 months of implantation.³⁷

Perforation may occur during the implantation or occur over time when a lead erodes through the myocardium. The incidence

of late lead perforation is thought to be < 1% based on manufacturer registry data.³⁸ Patient presentations ranged from asymptomatic, dizziness, and fatigue to symptoms of extracardiac pacing (e.g., chest wall pacing, hiccups, and intercostal muscle contractions), pericarditis, pericardial effusion, or tamponade (**Figure 45-12E**). A change from a left bundle branch block (LBBB) pattern to a right bundle branch block (RBBB) pattern on the ECG can represent a septal perforation. Chest radiographs or echocardiography may make the diagnosis but are not sensitive enough to exclude perforation. Computed tomography (CT) is widely available at all hours but provides only a static image and lacks specificity. Exact localization of the lead tip is limited by artifact. In a study of 100 patients with pacemakers who received unrelated chest CT scans, 15 were thought to have a cardiac perforation. This far exceeds all other estimates of lead perforation incidence. Diagnosis can be made by fluoroscopy. Management is by surgical or transvenous removal of the leads, both of which carry significant risks.^{36,39}

Extracardiac pacing is unusual with bipolar pacing leads as the current travels a very small distance between electrodes. Hiccups or chest wall complaints from diaphragmatic or intercostal pacing can occur with or without perforation of the RV wall. An insulation break, defect in the pacing wire, or other area of current leakage can stimulate the pectoral or other chest skeletal muscle. Changes in programming may minimize the stimulation until the defective component can be replaced.³⁷ Decreasing the pulse width and/or voltage output can minimize the stimulation until the defective component can be replaced.

Pectoral muscle stimulation is less common with the currently available bipolar pacemakers. An insulation break or defect in the pacing wire before it enters the subclavian vein will allow the current to flow into the pacemaker generator and cause skeletal muscle stimulation. This can also be seen with current leakage from the connector of the pacing wires or sealing plugs. In rare instances, erosion of the protective coating of the pacemaker generator can cause this phenomenon. Decreasing the pulse width and/or voltage output can minimize the stimulation until the defective component can be replaced.

THROMBOSIS

Thrombosis and stenosis of the veins (e.g., brachiocephalic or subclavian) or pacemaker leads are common (**Figure 45-15**).^{31,40} The incidence of thrombosis is unclear as many patients are asymptomatic. A prospective study of 145 patients with newly implanted leads found 23% developed venous thrombosis on Doppler ultrasound during follow-up at 3, 6, and 12 months. Only 3 of the 34 patients diagnosed with thrombosis had any signs or symptoms. An increased risk of thrombosis was seen with each additional pacemaker lead, hormone therapy, and history of thrombosis.⁴¹ Patients with thrombosis may present with ipsilateral arm swelling and discomfort. Patients may develop superior vena cava syndrome if the thrombosis propagates to the superior vena cava. Upper extremity deep venous thrombosis (DVT) requires anticoagulation and not removal of the leads.⁴² A thrombus can form in the right atrium.⁴³ Patients may present with symptoms of a pulmonary embolism.

FIGURE 45-15. Chest CT angiography demonstrating a large mass attached to the lead (white arrows) in the right atrium. LA, left atrium; RA, right atrium. (Used with permission from reference 40.)

INFECTION

CRMD poses a risk of infection. Infections can occur as a complication of implantation or in a long-implanted device.³¹ Incisional and pocket infections may present with erythema, fluctuance, tenderness, or dehiscence of the wound (**Figure 45-16**). *Staphylococcus* species are the most common organisms.^{1,44} *Staphylococcus* species adhere to polymers and create biofilms, which makes CRMD especially vulnerable to colonization. **Do not aspirate the pocket for cultures as this can cause damage the device or introduce infectious agents.** No clinical signs or symptoms will rule out spread of the infection from the pocket to the intravascular leads or endocardium. Draw blood cultures and begin empiric broad coverage for skin flora.

Infection of the leads or device-related endocarditis is much more serious. **Consider endocarditis in any patient with a pocket infection or a fever without a clear alternative source.** Patients may have an indolent course or present acutely ill with heart failure, sepsis, or septic emboli. The incidence of CRMD infection is 1% to 1.3%, but it carries a 3.7% to 11.3% mortality.³⁵

The diagnosis of a CRMD infection may be hard to make in the ED. There is no uniform gold standard. Diagnostic criteria include positive blood cultures, echocardiogram evidence of vegetations (e.g., on the leads, valves, or endocardium), absence of other causes for fever, and resolution of symptoms after device removal. Pocket infections can spread to intravascular leads and the endocardium without obvious local signs of inflammation. Bacteremia can seed an infection of a CRMD. *Staphylococcus* bacteremia from a documented non-CRMD source has been shown in one study to seed the CRMD in 36% of cases, with ICDs most vulnerable.⁴⁵

CRMD infections are especially hard to treat, with a recurrence rate of 50% without full lead extraction. The most significant risk factors for CRMD infection include postoperative hematoma, history of prior CRMD infection, end-stage renal disease, steroid use, diabetes mellitus, and an abdominal generator pocket.³⁵

Transthoracic echocardiogram may detect vegetations in only 23% of cases, compared to the transesophageal approach, which detects vegetations in 94% of cases.⁴⁶ Standard treatment has been at least 6 weeks of intravenous antibiotic therapy and device removal.^{1,47} Lead extraction, however, is technically challenging and carries significant risk of bleeding, perforation, or thromboembolic complications. CRMD infection has a recurrence rate of 50% with incomplete device removal.³⁵

ALLERGIC REACTIONS

Allergic reactions to the metal components of the pacemaker have been noted in the past. Current pacemaker generators and leads are coated with a substance to prevent the body from being exposed to the metal. Allergic reactions to the pacemaker covering are very rare but have been reported.

TWIDDLER SYNDROME

Twiddler Syndrome can be seen with any implantable subcutaneous device. Patients manipulate the device intentionally or unintentionally. This moves the pacemaker within the subcutaneous pocket, curling the leads (**Figure 47-17**).⁴⁸⁻⁵⁰ Higher risk is seen in the elderly from dementia, the obese from looser pockets, and in those with obsessive-compulsive disorders. Newer pacemakers are smaller and easier to turn. View the chest radiograph for any changes. The leads can be displaced from the pacemaker, displaced from the heart, or fractured.

This can result in syncope or pacing of structures if the device is providing impulses to other structures (e.g., abdominal muscle wall spasm, arm spasm, chest wall, diaphragm spasm, and hiccups). The patient may remain asymptomatic until they receive an inappropriate discharge or die from the device not working. The device can show problems associated with lead displacement or fracture. The device needs to be fixed by the specialist who inserted it. They will

FIGURE 45-16. Signs of a pocket infection. **A.** Skin changes 2 weeks after implantation. **B.** Pocket purulence. **C.** Pocket erosion. (Used with permission from reference 7.)

FIGURE 45-17. Chest radiograph of a patient with Twiddler syndrome. Note the twisted lead. (Used with permission from reference 7.)

replace the lead(s), reposition the lead(s), and secure the pacemaker in the pocket. This syndrome is not limited to pacemakers (e.g., ICDs, nerve stimulators, or ports). It is seen less commonly with defibrillators, which are bigger devices and harder to turn.

EMERGENCY EVALUATION OF PACEMAKER FUNCTION

Patients who present to the ED with a complaint that may be associated with their pacemaker require a thorough evaluation. True device malfunction is not as common as pseudo-malfunction. **Do not assume the pacemaker is the sole cause of a patient's symptoms.** This may delay care for other serious conditions. The myocardial interface is part of the closed circuit that allows a pacemaker to function. Any severe metabolic abnormality, conditions (e.g., ischemia or inflammation affecting the myocardium), or medications may interfere with pacemaker function (Table 45-2). Interrogate a pacemaker with a potential malfunction. **Do not defer other portions of the workup while awaiting interrogation.**

EMERGENCY MANAGEMENT

Assess patients with potential pacemaker malfunction for stability with the conventional “ABC” approach to the airway, breathing, and circulation. Place patient on a pulse oximeter and cardiac monitor. Obtain a full set of vital signs and an ECG. Have a low threshold to apply defibrillator pads in case the patient requires transcutaneous pacing or defibrillation, even if the patient appears hemodynamically stable. Obtain intravenous access. Identify and treat any immediate life-threatening conditions (e.g., hyperkalemia or acute ischemia).

WHAT DEVICE DOES MY PATIENT HAVE?

The simplest way to find out the kind and type of device is to ask the patient for their wallet ID card from the manufacturer. The patient may know their history, or the medical record may contain the type of device and the manufacturer. It is still very easy to identify the device by making a few calls.⁵¹ There are only five main manufacturers of CRMD, each with a 24-hour phone number to assist clinicians (Table 45-3). The manufacturer representative will have a database of their patients and can arrange interrogations.⁵¹ The appearance of the device on a chest radiograph can help identify the type of device and its manufacturer (Figure 46-3). An algorithm to identify devices based on the generator appearance on a chest radiograph has been made into a free mobile phone application called CRMD Finder.⁵¹

TABLE 45-3 Cardiac Rhythm Management Device Manufacturer Phone Numbers⁵¹

Manufacturer	Phone number

St. Jude	1-800-PACEICD
	1-800-722-3774

CHEST RADIOGRAPHY

Obtain overpenetrated posteroanterior and lateral chest radiographs. This is helpful in locating the generator and lead positions. Look for a loose connection where the lead connects to the pacemaker generator. Manipulation of the pulse generator within the pocket may relieve or reproduce the patient's problem. A pneumothorax and/or hemothorax may be detected in patients whose pacemakers have been recently implanted (Figure 45-12A).

The pacemaker lead may have become dislodged from its implantation site. This is extremely uncommon with current systems, as they have safety mechanisms to prevent lead dislodgement. Ensure that the distal end of the pacing wire is within the cardiac silhouette and against the myocardium. It may be free-floating within the ventricle or may have perforated the ventricular wall. Obtain previous chest radiographs and compare them to the current radiographs to help determine if the leads have been displaced.

Lead fractures can occur anywhere along the length of the pacing wire (Figure 45-14A). They most often occur at stress points adjacent to the pacemaker or just under the clavicle as the pacing wire enters the subclavian vein. The lead has a J-shaped retention wire to help maintain its shape. The tip of the retention wire may occasionally protrude from the plastic-coated lead. This protruding wire has the potential to puncture the right atrium or superior vena cava and cause a hemorrhagic pericardial effusion that may result in cardiac tamponade (Figure 45-12E).

HISTORY

Carefully obtain a history to avoid premature limiting of the differential diagnosis. Gather information from the family members, medical records, records from nursing facilities, or outside records as needed. Dizziness, near-syncope, palpitations, syncope, or any symptom that may resemble those prior to pacemaker implantation may reflect a potential pacemaker malfunction. Pertinent device history includes the type of device, when it was placed, and why it was placed. **A pacemaker-dependent patient may be in immediate danger if the device is not functioning.** Other patients may only need the device as a backup. Inquire about the most recent device check, battery change, and any recent reprogramming. Trauma or other manipulation may dislodge the leads from the myocardium, dislodge the leads from the generator, or damage the leads. Direct trauma over the pacemaker generator can render it inoperable. Inquire about infection risks (e.g., immunocompromised, injection drug use, or sources of potential bacteremia).

PHYSICAL EXAMINATION

Perform a thorough examination of the patient. Observe the vital signs for bradycardia, fever, hypertension, hypotension, or tachycardia. Evaluate the veins of the head and neck for venous engorgement

TABLE 45-4 Summary of the ECG Evaluation

1. Does the ECG suggest a condition (e.g., bradycardia, hyperkalemia, or ischemia) that needs immediate action?
2. Is the heart rate inappropriately fast, inappropriately slow, or have long pauses?
3. Atrial pacing and sensing: Are intrinsic P waves visible? Is the pacemaker sensing them, and is the pacemaker properly inhibited?
4. Atrial capture: Is each atrial pacer spike followed by a paced P wave?
5. Ventricular pacing and sensing: Are there intrinsic QRS complexes? Is the pacemaker sensing them and properly inhibited?
6. Ventricular capture: Is each ventricular pacer spike followed by a paced QRS complex?

suggesting a central venous thrombosis or a superior vena cava syndrome. Edema of the ipsilateral upper extremity indicates thrombosis and possible occlusion of the subclavian vein. Identify the location of the pacemaker pocket and implantation scar. Note if the pacemaker generator has moved from its original position. This can result in a partial or complete disconnection of the leads from the generator. Inspect the pacemaker pocket for signs of infection (i.e., a discharge, edema, skin erosion, erythema, redness, tenderness, and/or warmth).

ECG INTERPRETATION

A systematic approach to the paced ECG can help narrow the differential diagnosis when pacemaker malfunction is suspected (Table 45-4). Identify any signs of bradycardia, ischemia, or hyperkalemia that need emergent action and characterize pacemaker function. Consider obtaining a long rhythm strip for more data. Bipolar leads have very small pacer spikes that may not be visible in every lead. The lead is usually implanted in the RV with a typical paced QRS complex having an LBBB (Figures 45-9, 45-18, 45-19, and 45-20). An RBBB pattern may be normal in 17% of patients with RV pacing.⁵² Patients with biventricular pacing may have an

RBBB pattern. A new change from LBBB to RBBB suggests migration of the lead into the LV, potentially from perforation. Compare the axis of the pacer spike and QRS complex to an old ECG. Any change in axis suggests lead migration.

Determine whether the patient is presently paced and in what chamber. The QRS morphology of an intrinsic beat will be different and may have a different axis from a paced beat (Figures 45-9A and B). A paced beat occurs immediately after a pacer spike (Figure 45-9B). **Fusion or pseudo-fusion beats occur when the pacemaker fires on an intrinsically occurring P wave or QRS complex and are not signs of pacemaker malfunction (Figures 45-9C and D).** A fusion beat is a QRS complex that has been formed by depolarization of the myocardium that was initiated by both the pacemaker spike and the patient's intrinsic electrical activity (Figure 45-9C). The QRS morphology of a fusion beat is a hybrid of the intrinsic and paced QRS morphology. **A pseudofusion beat is a QRS complex formed exclusively by the patient's intrinsic electrical activity and resembles the intrinsic QRS complex (Figure 45-9D).** A pacemaker stimulus is fired just before the intracardiac voltage to activate the sensing circuit and inhibit the pacemaker so the pacemaker spike appears toward the end of a pseudo-fusion QRS complex.

A properly functioning pacemaker will sense intrinsic cardiac electrical activity. A pacemaker spike will be seen followed by a QRS complex in a single-chamber or ventricular pacemaker if the intrinsic cardiac activity is below the programmed rate (Figure 45-18). A pacemaker spike will be followed by a P wave and a second pacemaker spike will be seen followed by a QRS complex if the patient has a dual-chamber pacemaker (Figures 45-19 and 45-20). No pacemaker spike will be seen on the ECG if the intrinsic cardiac electric activity is above the programmed rate.

Patients with CRT are usually paced continuously. A biventricular pacing ECG will usually have an atrial and two closely spaced RV and LV pacing stimuli (Figure 45-21). The coordinated RV and LV depolarizations result in a hybrid QRS that is usually narrower

FIGURE 45-18. A 12-lead ECG of a single-chamber or ventricular pacemaker.

FIGURE 45-19. A 12-lead ECG of a dual-chamber or atrioventricular sequential pacemaker.

FIGURE 45-20. Schematic of an ECG monitor strip of a dual-chamber pacemaker. Atrial (*first arrow*) and ventricular (*second arrow*) pacing spikes are clearly visible.

than that of RV pacing. Lead positions are variable in CRT, resulting in variable ECG morphology.

IMAGING

Obtain a posteroanterior and lateral chest radiograph to best visualize the device, lead dislodgement, insulation breaks, or fracture. Obtain a single portable radiograph if the patient is unstable. Order an additional overpenetrated view of the device if using the radiograph to help identify the device, and be explicit in your request to the technician.

The chest radiograph can reveal the number and appearance of leads, the appearance of the pulse generator, and the manufacturer-specific radiopaque alphanumeric codes (ANC). Identification of

FIGURE 45-21. ECG monitor strip demonstrating biventricular pacing.

the ANC was less than 20% accurate on chest radiographs using standard resolution of a hospital electronic medical records system.⁵¹ View the radiographs on a radiology monitor if possible. The number of leads and their position can help distinguish a single- or dual-chamber pacemaker with leads to only the RV. A CRT device has a third lead to the LV. Pacemaker leads are uniformly thin. ICDs and CRT-Ds will have leads that have segments of thicker shock coils. Devices with ICDs have a significantly bigger pulse generator than a pacemaker alone because they have both a battery and a similarly sized capacitor to store the higher voltage needed for defibrillation. A device with an ICD will have two radiopaque shadows within the generator. An algorithm to identify devices based on radiograph appearance of the generator was published in 2011 and has been made into a free mobile phone application (i.e., CRMD Finder).⁵¹

Look for complications in recently placed devices from the procedure (e.g., a pneumothorax). Confirm the leads are in the correct position. Old radiographs allow comparison for changes. A right atrial (RA) lead enters the RA and curves superiorly to reach the RA appendage. This forms a J shape on the lateral chest radiograph with the tip running medially and anteriorly. The RV lead will be L-shaped, run anteriorly and medially, and the tip near the apex. The LV lead of biventricular devices goes through the coronary sinus to the lateral or posterior wall of the LV through the cardiac veins. The LV lead on a posteroanterior radiograph may have a serpentine course running laterally or may be hard to distinguish from an RV lead. It will run posteriorly on the lateral radiograph.⁵³

Other imaging may be obtained. An echocardiogram is the test of choice when suspecting device infection, lead dislodgement, lead perforation, pacemaker syndrome, or tricuspid regurgitation from lead placement. CT can also evaluate lead dislodgement or perforation. The CT scan is limited by its static nature and artifacts from the metal in the generator and leads. The advantages of CT are its wide availability and the potential to diagnose other etiologies of the patient's symptoms. Fluoroscopy provides a definitive diagnosis when there is a suspicion for lead dislodgment or lead perforation or other imaging modalities are not diagnostic.³⁹ Ultrasound can detect thrombosis in an upper extremity. Superior vena cava syndrome can be a clinical diagnosis confirmed and differentiated from pulmonary embolism by contrast CT. Contrast venography is the gold standard for diagnosis of superior vena cava syndrome and may be helpful for surgical planning.⁵⁴

ADDITIONAL STUDIES

Obtain laboratory studies tailored to the clinical situation. Always obtain medication levels for cardiotoxic drugs, electrolytes, and glucose levels. Consider blood cultures for endocarditis or bacteremia, troponin for ischemia, and a lactate for infection. Order a formal device interrogation and consult the patient's Cardiologist.

MAGNET EXAMINATION

The magnet examination turns off the pacemaker's sensing function. A doughnut-shaped magnet is made for this procedure (Figure 45-22). A generic magnet may be used in the absence of a pacer magnet. Two magnets may be required in the obese patient or those whose generator is under the pectoral muscles. The magnet examination is usually safe, and its effects do not last once the magnet is removed. The magnet examination is performed routinely at clinic evaluations and remotely from home when a patient is established and compliant.

The magnet can distinguish oversensing from component failure as the cause of failure to pace. The magnet can terminate pacemaker dysrhythmias that depend on sensing. The magnet examination

FIGURE 45-22. An example of a pacemaker magnet.

also supplies information on battery depletion. Pacemakers at the end of their battery life are unpredictable. **Be prepared with staff and equipment in case of an emergency to start transcutaneous or transvenous pacing. Be prepared to defibrillate in the unlikely event that asynchronous pacing on an intrinsic T wave initiates VT or VF. Have Advanced Cardiac Life Support (ACLS) medications readily available.**

Place the magnet over the pacemaker generator while simultaneously obtaining a 12-lead ECG and rhythm strip. The magnetic field causes the reed switch inside the pacemaker to close. This bypasses the sensing amplifier and converts the pacemaker into the asynchronous (i.e., VOO or DOO) mode (Figure 45-23). The pacemaker fires at the manufacturer-specific asynchronous rate, which is usually between 60 and 80 beats per minute. The magnet rate may be slower if the battery is nearing the end of its life. The magnet examination results are unpredictable if the battery is at the very end of its life. Pacemaker spikes occurring during the refractory period of an intrinsic QRS complex will not be captured (Figure 45-23B).

The application of the magnet over a generator pacing inappropriately slowly or with unexpected pauses can show a variety of results. The pacemaker will pace asynchronously at a programmed rate if it is working properly. This indicates that the failure to pace the myocardium in a patient with bradycardia is due to oversensing. The unit may be sensing a large T wave as a QRS complex. Alternatively, it may be sensing a normal T wave as a QRS complex if the QRS complexes are small in amplitude. Tape the magnet over the pacemaker generator if the bradycardia is corrected. A pacemaker continuing to pace slowly or having inappropriate pauses

FIGURE 45-23. Schematic of a ECG monitor strip. **A.** Pacemaker activity without a magnet applied. **B.** Pacemaker activity with a magnet applied.

suggests a failure of a component in the system (i.e., battery, generator, or leads). The battery may be depleted or the set rate has been changed if the pacemaker spikes occur at less than the programmed rate. Rarely is the pacemaker in a “sleep mode” that is based on time of day.¹⁵

The magnet will work on a combination of pacemakers and defibrillators. The magnet application does not affect the pacemaker. The magnet switches the reed switch to turn the defibrillator off. This lasts until the magnet is removed.

PACEMAKER INTERROGATION

Pacemakers store a record of each sensed and paced event, which allows a determination of undersensing and oversensing. It also provides other information (e.g., arrhythmia logs, battery life, heart rate range, ICD discharges, lead integrity, and percentage of time pacing).²¹ **The device interrogation by the manufacturer representative or cardiology technician is a critical part of the emergency evaluation of a patient presenting with symptoms that might be attributed to the pacemaker.** Each manufacturer can arrange interrogation through their 24-hour phone line (Table 45-3). The interrogator may be able to identify problems and reprogram the device to avoid an admission in consultation with the patient's Cardiologist.¹⁶

OTHER MANAGEMENT CONSIDERATIONS

DIAGNOSING ACUTE CORONARY SYNDROME

Early diagnosis and reperfusion of acute coronary occlusion are critical to reducing mortality.⁵⁵ Patients with a paced rhythm and myocardial infarction are less likely to have emergent reperfusion and have a higher mortality at 30 days and 1 year.⁵⁶ Ventricular pacing makes the ECG diagnosis of acute ischemia more challenging, but ECG can still be diagnostic. Repolarization causes baseline discordant ST-segment and T-wave abnormalities in the opposite direction of the majority of the QRS deflection like the ECG in nonpaced LBBBs. Sgarbossa criteria were first used in LBBB to diagnose acute myocardial infarction and then applied in pacemaker patients. These criteria were highly specific but had only a 20% sensitivity.⁵⁷ Modified Sgarbossa criteria performed better to diagnose acute coronary occlusion requiring reperfusion (Table 45-5).⁵⁸ A validation study showed 80% sensitivity and 98% specificity in LBBB patients.⁵⁸ Case reports show that modified Sgarbossa criteria have been successfully applied to patients with paced ventricular rhythms.^{59,60} The presence of any one of the three criteria would fulfill modified Sgarbossa criteria and support the diagnosis of an acute coronary occlusion or “ST-segment elevation myocardial infarction (STEMI) equivalent” in a patient with an LBBB or paced ventricular rhythm.

Even less evidence is available for the ECG diagnosis of acute coronary occlusion in biventricular pacemaker patients. The baseline ECG morphology is variable because the QRS is a combination of RV and LV depolarization and lead locations are variable. Case reports show that biventricular pacemaker patients who have acute coronary occlusion may meet conventional STEMI criteria, Sgarbossa criteria, or modified Sgarbossa criteria.⁶¹⁻⁶³

TABLE 45-5 Modified Sgarbossa Criteria to Predict Acute Coronary Occlusion⁵⁸

1. ST elevation ≥ 1 mm in same direction (concordant) as QRS complex in any lead
2. ST depression ≥ 1 mm in any lead from V_1 to V_3
3. ST elevation \div S-wave amplitude exceeding 0.25 in any lead

ACLS CONSIDERATIONS

ACLS can be performed in CRMD patients as usual with a few additional considerations. Be prepared to apply external defibrillation as necessary. Tape a magnet in place to avoid unintentional ICD shocks during the resuscitation. Most ICDs are programmed to do no more than five successive shocks to preserve battery life.²⁸ Changes in pacing and defibrillation thresholds are seen with metabolic derangements of critical illness, a pneumothorax from cardiopulmonary resuscitation (CPR), and resuscitation medications (e.g., amiodarone and lidocaine) (Table 45-2). This may lead to oversensing or undersensing.³⁴

Apply cardioversion and defibrillation pads at least 8 cm from the device, with the current path perpendicular to the plane of the pacing system. Placement of the pads directly anterior and posterior to the LV is recommended when possible. Do not delay emergent defibrillation to reposition the pads. ICD shocks are not dangerous to rescuers doing CPR or monitoring equipment. The device requires interrogation after cardioversion or defibrillation to assure return to appropriate settings.^{28,34}

Central venous access using the femoral vein is preferred when a CRMD is in place because chronic thrombosis associated with leads may be present in the subclavian vein. Guidewire contact during placement may trigger a response from the device.³⁴

FUTURE CRMD TECHNOLOGY

LEADLESS PACEMAKERS

Many of the complications of ICDs and pacemakers are related to transvenous leads and subcutaneous pockets. Leadless ICDs and pacemakers have been developed (Figures 45-24 and 45-25).⁶⁴⁻⁶⁶ Leadless pacemakers are an emerging technology that includes all components of a pacemaker system in a device the size of a large pill placed directly into the RV apex and attached to the myocardium. Complication rates compare favorably to conventional pacemakers, but this technology is currently limited to single-chamber pacing.⁶⁷ Subcutaneous ICDs (i.e., S-ICD) are tunneled within the chest wall and have the comparable ability to detect and terminate ventricular tachyarrhythmias but lack backup pacing abilities and antitachycardia pacing.⁶⁸

REMOTE MONITORING

Remote monitoring (RM) of CRMDs is already available from every major manufacturer. Patients may be alerted to a malfunction and present to the ED as this technology becomes more widely adopted. RM CRMDs have a built-in micro-antenna that continuously and wirelessly transmits information (e.g., arrhythmia information, battery status, heart rate ranges, lead impedance, and programming).

FIGURE 45-24. Examples of a single-component leadless pacemaker. The Micra (Medtronic, Minneapolis, MN) and the Nanostim (St. Jude Medical, St. Paul, MN) are next to each other for size comparison. (Used with permission from reference 30.)

FIGURE 45-25. Leadless pacemaker fixation mechanism and radiographic appearance. Nanostim active fixation leadless pacemaker (St. Jude Medical, St. Paul, MN) is on the left and the Micra passive fixation transcatheter pacing system (Medtronic, Minneapolis, MN) is on the right. (Used with permission from reference 30.)

They allow the patient to use their cell phone or tablet to securely transmit the data. The pacemaker alerts the patient and Cardiologist of any detected change in clinical condition or malfunction. **RM can identify problems (e.g., impending battery or lead failure) before they become clinically apparent.** These transmissions are not currently in real-time but reviewed during office hours.⁶⁹

Multiple large, prospective studies have shown RM to be cost efficient, reliable, and safe. Health care utilization decreased by 45% in one study, mainly as a result of reduced office visits. Most RM use is currently for ICD and CRT-D devices, which require follow-up every 3 to 6 months and have a shorter, less predictable battery life than pacemakers.⁶⁹ A prospective study of a quarter of a million consecutively implanted RM-enabled devices from 2008 to 2011 demonstrated that 53% of patients never used the RM feature.⁷⁰

OTHER DEVELOPMENTS

Other developments have occurred in the area of pacemakers and defibrillators. Mesh antibacterial envelopes can be used to cover the implanted devices. They release antibiotics after implantation as they dissolve. Antibacterial envelopes may decrease the pocket infection rates. They also stabilize the device, preventing migration.

Solar-powered pacemakers have been developed.^{71,72} They solve the problem of the current battery lasting 5 to 12 years. They use sunlight as an alternative power source. A small amount of light can penetrate the skin. It has been suggested that the solar cell be implanted in the neck. It only takes a few minutes of sunlight to charge the device for 24 hours.

MRI-compatible devices have been developed. A sensor automatically puts the device into the safe mode when the patient enters the

MRI. This pauses the device only when the patient enters the MRI machine. It requires the Cardiologist to turn on the sensor.

SUMMARY

CRMDs have become more common and complex. The Emergency Physician needs a working knowledge of this technology and a systematic approach to evaluate these patients. Safety features have greatly reduced pacemaker dysrhythmias and malfunctions. Pseudo-malfunctions are more common than true malfunctions. Consider the integrity of the entire pacemaker circuit, including the myocardium, and nonpacemaker etiologies of a patient's presentation. Disruption to the myocardial-pacemaker interface is common. Immediately life-threatening conditions (e.g., hyperkalemia and ischemia) may affect pacemaker function. Device interrogation and Cardiologist consultation are critical steps but should not defer the workup of other emergent conditions.

Automatic Implantable Cardioverter-Defibrillator Assessment

Carlos J. Roldan

INTRODUCTION

The introduction of implantable cardioverter-defibrillator (ICD) technology has revolutionized the fields of cardiology and electrophysiology. More than 100,000 such devices are implanted annually in the United States alone. ICDs allow life-threatening ventricular tachycardia and ventricular fibrillation to be safely controlled and benefit patients at risk for sudden cardiac death. Multiple studies have examined the prophylactic indication for ICD therapy in high-risk groups.¹⁻⁷ The ICD has become a more common therapeutic option for Brugada syndrome, prolonged QT syndrome, and cardiomyopathies.⁸

An ICD is often placed prophylactically to prevent sudden cardiac death from ventricular arrhythmias. An ICD follows an algorithm and applies a full-energy shock, a low-energy shock, or it can overdrive pace the heart. All ICDs have a pacemaker function that can be set. Some ICDs can transmit to remote monitors.

The Emergency Department is often the initial contact point for these patients. Emergency Physicians must be familiar with the problems that can be encountered by a patient with an ICD.⁹⁻¹³ This chapter describes technical aspects, basic interrogation of the device, and a general approach to a patient who presents to the Emergency Department with an ICD.

TECHNICAL CONSIDERATIONS

The ICD has four main functions. It recognizes and records local atrial and ventricular electrogram signals. It then classifies the sensed signals to programmable heart rate zones. The ICD provides a shock to terminate ventricular tachycardia or ventricular fibrillation. It has a pacing capability for bradycardia and/or cardiac resynchronization therapy. Therapy to terminate the arrhythmia is initiated with a high-energy shock of up to 40 J when detection criteria are satisfied.

ICD technology has progressed exponentially since its introduction in the early 1980s.¹⁴ The ICD system is comprised of a pulse generator, a battery, and a lead system. The lead system is required for sensing, pacing, and the delivery of therapy. The earliest systems required that the pulse generators be placed abdominally due to their large size (**Figure 46-1**). Defibrillation was delivered via two epicardial patches positioned anteriorly and posteriorly. A transvenous spring electrode in the superior vena cava was occasionally used with an epicardial patch. Sensing was achieved through separate epicardial screw-in electrodes. Initial lead placement required a sternotomy, lateral thoracotomy, or a subxiphoid approach, which made early implants quite cumbersome.¹⁵

The smaller size devices used now allow for superficial implantation of the pulse generator in the anterior chest wall (**Figure 46-2**). The current ICD systems are comprised of three main parts (**Figure 46-3**). The pulse generator is programmable and capable of analyzing and recording the patient's heart and rhythm. The ICD generator houses the batteries, high-voltage capacitors, and microprocessors necessary to process sensed intrinsic cardiac electrical activity.

FIGURE 46-1. Abdominal placement of the ICD generator. Initial implants required a thoracotomy to position the epicardial patches needed for defibrillation and the screw-in sensing leads. The leads were tunneled abdominally to the ICD generator.

FIGURE 46-2. The current nonthoracotomy system. The development of smaller generators and biphasic waveforms for defibrillation allowed for transvenous positioning of the ICD leads and a pectorally located generator.

The generator is a minicomputer within a hermetically sealed titanium can (e.g., case) capable of generating shocks. Typical ICDs contain lithium silver vanadium oxide cells that store between 2 and 7 volts.¹⁶ The high voltages necessary for defibrillation are generated with the aid of high-voltage capacitors that generate 700 to 800 volts of defibrillation energy in under 20 seconds. ICD leads can be inserted in different combinations such as a single wire in the right ventricle (e.g., single-chamber ICD), two leads (e.g., in the right atrium and right ventricle, or a dual-chamber ICD), or three leads (i.e., biventricular ICD with one in the right atrium, one in

the right ventricle, and one on the outer wall of the left ventricle; **Figure 46-3**). The leads are required for sensing, pacing, and the delivery of therapy. The final component is the battery to power the ICD system.

ICD implantation has evolved quite rapidly due to advancements in lead technology, generator technology, and the development of biphasic defibrillation waveforms, which lowered the energy requirements necessary for successful defibrillation.¹⁷ The creation of a lead combining pacing and sensing capabilities with a high-voltage electrode coil allowed for nonthoracotomy system implants with reduced surgical morbidity and mortality.¹⁸ The leads are positioned transvenously via the subclavian vein and fixed to the inside of the right ventricle. The leads were once tunneled subcutaneously to the abdomen due to the large generator size of early defibrillators. Technology has advanced to the development of more compact generators. The smallest commercially available devices today are under 40 cm³ and weigh well under 100 gm. Smaller generators allow for subcutaneous pectoral implantation and simplification of the implantation process (**Figure 46-2**).¹⁶

Current ICDs allow extensive programmability for tiered antichycardia pacing (ATP), tiered high-voltage therapies, single- or dual-chamber bradycardia pacing, supraventricular tachycardia discrimination algorithms, and detailed diagnostics of tachycardic and bradycardic episodes. Implantable loop recorders and home monitoring functions extend the technical capabilities for automatic detection of arrhythmias that may not be symptomatic. It allows for fully automatic and wireless data transmission, including episode counters.^{15,17} This allows alterations in device programming or medication dose modifications in the outpatient setting and avoids hospitalization.^{19,20}

ATP is also known as overdrive pacing. It may be enabled to manage ventricular tachycardia (**Figure 46-4**).²¹⁻²³ ATP commonly consists of a burst of pacing (i.e., 6 to 10 beats) at a rate faster than the ventricular tachycardia rate. ATP may be felt by the patient. It is painless and often terminates the ventricular tachycardia before the

FIGURE 46-3. Assessing the ICD. **A.** Chest radiograph of a patient with a biventricular ICD. Note the right atrium (RA), right ventricle (RV), and left ventricle (LV) leads connected to the header. The RV lead has a combination of RV pace/sense lead, RV coil, and superior vena cava (SVC) coil. The subcutaneous (SC) coil is connected to the SVC port. Another set of RA and RV abandoned leads can be seen from a previous device implantation. **B.** The Transoma Medical implantable loop recorder. each interval, device classifications of therapy success, energy, episode plots, impedance values for shocks, intracardiac electrograms, and textual episode descriptions. This diagnostic information can be extremely valuable to determine whether programming changes should be made.²⁷

BATTERY AND CAPACITORS

Battery longevity is significantly different among manufacturers. Battery voltages and capacitor charge times must be noted. Capacitors with smaller or larger capacities and changes in the initial shock polarity have not significantly improved defibrillation efficacy.²⁸ A variation in the number and position of electrodes can significantly influence the defibrillation threshold.²⁸ Several factors are associated with service life of ICD devices. Differences in longevity emerged among systems and manufacturers.

Generator replacement is usually recommended when voltages fall below the elective replacement indicator (ERI), which is approximately 2.6 volts. The battery has reached its end of life (EOL) when the battery voltage falls below 2.2 volts. This signifies a more urgent need for battery replacement. The need to replace a generator is also dependent on capacitor charge times. The occurrence of two consecutive charge times greater than 16 seconds is considered prolonged and may warrant urgent replacement regardless of the battery voltage. Automatic capacitor reformation is usually set to every 6 months to replenish their charge. This function can be programmed at preset time intervals. More frequent reformation is required and performed as the device reaches the battery EOL and based on manufacturers' recommendations.

LEAD INTEGRITY

There was concern in the past about the long-term reliability of chronically implanted leads because an insulation defect or conductor disruption could lead to ICD lead failure. Lead failure can affect the high-voltage lead or the pace-sense circuit of the lead. Most ICDs now provide lead-impedance monitoring for early detection of lead failure. An abnormal impedance indicates conductor fracture or insulation defect. An audible signal or vibration notifies the patient, who should then immediately contact their Cardiologist or present to the Emergency Department. Retrospective data from single centers suggest a potential clinical benefit of patient notification for ICD lead failure detection.²⁹

Various parameters are checked to ensure lead integrity (e.g., pacing thresholds, lead impedance, and the size of intracardiac R waves). A pacing threshold of ≤ 1.0 volt at a pulse width of 0.5 milliseconds is desired at the time of implantation. An acute rise in threshold may be seen initially and generally falls with time. Chronic thresholds range between 0.5 and 2.0 volts. Epicardial leads generally exhibit higher thresholds. Any change in thresholds must be compared with prior trends to assess its significance. Pacing thresholds may also change with the administration of antiarrhythmic drug therapy. Potential complications of ICD lead failure include oversensing of electrical noise, undersensing of ventricular tachyarrhythmias, inappropriate therapy, and lethal antiarrhythmic therapy.³⁰

Modern ICDs perform serial impedance measurements automatically. It is unlikely that such discrete measurements will reveal abnormal impedance if lead failure causes sporadic dysfunction. Multiple impedance measurements per day may be necessary to enhance the sensitivity of the patient alert.³¹ Lead impedances will vary based on the type of lead. The high-voltage impedance measurement differs between devices.³² Normal impedances range from 300 to 1200 ohms. A sudden change in impedance may signal a problem with lead integrity. A high impedance reading suggests the

FIGURE 46-5. A lead fracture. (Photo used with permission from reference 33.)

possibility of lead fracture (**Figure 46-5**).³³ A low impedance reading indicates a problem with the insulation. The impedance of the high-voltage coil must also be evaluated.

Epicardial and active can systems demonstrate lower impedance values compared to endocardial systems due to their larger surface area. Normal values generally range between 20 and 80 ohms. High impedance values usually indicate a fracture in the defibrillation system. Any stark changes in impedance levels may suggest a patch problem (e.g., crinkling, migration, or seroma formation). Any impedance change in an endocardial system may indicate lead dislodgement.

R-wave amplitude is a direct measure of intracardiac electrogram activity and determines the device's ability to sense. An R wave of ≤ 5 millivolts is desired at implantation to ensure adequate detection of ventricular fibrillation. The most common explanations for a decrease in R-wave amplitude after an implant are lead dislodgment or local factors (e.g., edema or fibrosis). This change may be associated with an increase in lead impedance and pacing thresholds.

ANALYZING APPROPRIATENESS OF THERAPY

Current ICDs have simultaneous marker channels with real-time intracardiac electrograms (**Figure 46-6**). It is important to document intracardiac activity during sinus rhythm. These electrograms can be used as a basis of comparison with tachycardia events. Examine the signals for evidence of noise, which may be an indicator of sensing problems, a connector issue, or a faulty adaptor. Electrograms must be examined during various maneuvers (e.g., arm maneuvers, bending, and deep breathing).¹¹ Examine intracardiac electrograms for T-wave oversensing or detection of pacemaker spikes as ventricular signals.^{11,34} Rule out oversensing by the atrial lead in dual-chamber devices.¹¹ Wide variations in electrogram size may suggest that the lead is not stable or well fixed.

THE ICD IN THE EMERGENCY DEPARTMENT

A patient with an ICD may present to the Emergency Department for various reasons. Manufacturers offer 24-hour technical support. They maintain a registry of devices implanted and evaluations performed. **A staff of field engineers is often available for help with the assessment, interrogation, and management of ICD function.** The ICD may be interrogated by the Emergency Physician.^{35,36}

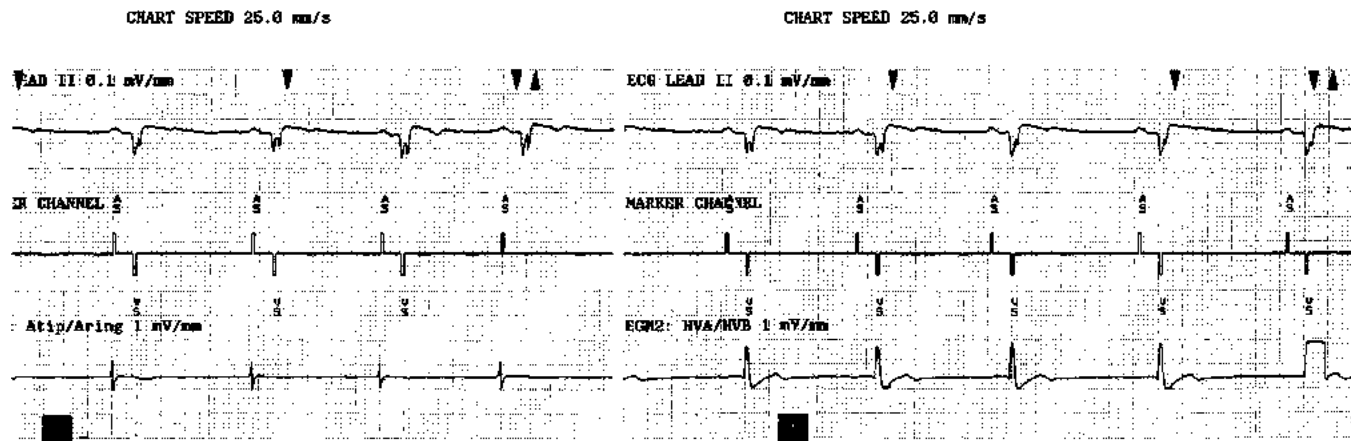

FIGURE 46-6. The intracardiac electrogram as recorded by the ICD. Printouts were obtained from a Medtronic Gem II DR dual-chamber ICD. The first line shows lead II of an ECG rhythm strip. The marker channel directly under the rhythm strip indicates behavior (i.e., sensing and pacing) in each chamber. The third line represents the intracardiac electrogram from the atrium (left) and ventricle (right). Measured in millivolts per millimeter, larger signals imply better sensing.

It can result in a faster ICD interrogation versus waiting for a field engineer to come to the Emergency Department. **The U.S. Food and Drug Administration (FDA) is responsible for assessing the premarket safety, postmarket safety, and effectiveness of medical devices marketed in the United States. They require manufacturers to submit annual reports detailing the number of device implants and malfunctions that have occurred.**³⁷

Individuals with recently implanted devices may be quite anxious and may seek medical attention after a single ICD discharge. Patients may present after multiple ICD discharges or in full cardiac arrest. The warmth, local redness, and pain associated with a potential infection of the ICD pocket may prompt the individual to seek medical attention (Figure 46-7).

Patients with ICDs must be placed on continuous telemetry. Perform a detailed and complete history and physical examination. Question the patient regarding the number of shocks received, symptomatic palpitations, presyncope, symptoms of congestive heart failure, or symptoms consistent with angina. Examine the pocket site for evidence of local infection, including warmth, tenderness, and discharge. Upper extremity or neck swelling ipsilateral to the inserted endocardial lead suggests the possibility of a subclavian vein or superior vena cava thrombosis.³⁸ Bilateral head edema and neck vein swelling suggest the possibility of a superior

vena cava thrombosis or superior vena cava syndrome. Document any changes in medications or whether antiarrhythmic therapy has recently commenced. Obtain routine blood work (e.g., complete blood count, serum electrolytes, magnesium level, renal function indices, cardiac enzymes, troponin, and quantitative levels of measurable medications).

Identify the ICD model. Patients are generally given identification cards that list the manufacturer, lead system, generator model, and a 24-hour emergency contact number. This information is often not available from the patient in the Emergency Department. An overpenetrated chest radiograph showing the generator in an emergency can demonstrate the radiopaque identifier of the manufacturer (Figure 46-3).

The chest radiograph may be of diagnostic importance. It is not only important for device identification but can also give useful information about lead integrity (Figures 46-3 and 46-5).³⁹ A chest radiograph is routinely performed to assure lead positioning and slack in the lead and to rule out other thoracic pathology.⁴⁰ The chest radiograph is an excellent tool in patients with the older epicardial patch system to demonstrate patch crinkling, fracture, or migration. The leads can be assessed for fractures or discontinuities with endocardial systems (Figures 46-3 and 46-5). Fractures can occur anywhere along the lead. They are most commonly seen near the junction of the first rib and the clavicle, a condition referred to as “subclavian crush.”

Make attempts to obtain a 12-lead electrocardiogram (ECG) before any interventions are made to terminate the arrhythmia if the patient presents with a ventricular arrhythmia and is hemodynamically stable. This may be difficult due to concomitant discharges from the device, an anxious staff, and an anxious patient. Antiarrhythmic medications (e.g., amiodarone, beta-blockers, and procainamide) may have to be considered in the event of recurrent ventricular tachycardia.

EMERGENCY DEACTIVATION (MAGNET BEHAVIOR)

The ability of an ICD to identify and treat tachyarrhythmias can be temporarily disabled with the use of a magnet (Figure 46-8).⁴¹ This situation may arise in the setting of multiple ICD discharges where the shocks are not tolerated or prior to a surgical procedure where electrocautery is necessary. Emergency deactivation with a magnet can result in serious complications (e.g., causing a battery indicator to switch to “end of life” or the loss of some

FIGURE 46-7. A pocket infection with scabbing. (Photo used with permission from reference 61.)

FIGURE 46-8. An example of a magnet to disable the ICD.

antitachycardia therapies).⁴² **The application of a donut-shaped magnet (Figure 46-8) overlying the ICD pulse generator forms a magnetic field that trips a reed switch in the ICD generator circuit.¹¹** This results in a suspension of tachycardia detection and therapy delivery. A single magnet will suffice in most cases. Two or more magnets may be required to achieve deactivation in obese patients or in the presence of pockets with significant edema.⁴³ **The patient must be fully monitored, a cardioverter-defibrillator unit must be readily available, and Advanced Cardiac Life Support (ACLS) medications must be readily available if an ICD is to be deactivated.**

The magnet response of an ICD varies subtly from manufacturer to manufacturer. The application of a magnet to Medtronic devices temporarily disables tachycardia detection and therapy with no effect on bradycardia pacing. Removal of the magnet will resume arrhythmia detection. Newer Medtronic ICDs will elicit a continuous beep lasting for 15 seconds if a magnet is placed directly over the ICD. A magnet applied over Guidant ICDs also inhibits tachycardia therapy with no effect on bradycardic pacing. These devices will generate beeping tones, which change to a continuous tone. The constant tone indicates that the device is off and will not deliver tachycardia therapy. The device can be turned back on by reapplying the magnet over the ICD for 30 seconds. Tones will now change from continuous to beeping synchronous with R waves, signifying that the device is on again. Newer generation Guidant ICDs have a built-in electrocautery feature that can be activated by use of the Guidant programmer. This will suspend tachyarrhythmia therapies and pace in the DOO mode. Regular functioning of the ICD is restored by turning this feature off.

ICD DISCHARGES

Patients who experience a shock but feel unwell after the event or who receive more than one symptomatic ICD therapy within a short time (i.e., minutes to hours) require emergent evaluation.⁴³ Most ICDs have a limit to the number of shocks they can generate before they stop producing shocks. This number is usually five to seven shocks. The ICD can reset and start shocking the patient again to the set maximum number of shocks if the cardiac rhythm reverts to normal sinus rhythm. Multiple ICD discharges or shocks in a short time can cause severe battery depletion. **Possible etiologies that warrant medical attention include ongoing arrhythmias not adequately treated by the device, myocardial infarction, electrolyte imbalances, and ICD malfunction.**

Emergency Department patients presenting with multiple ICD discharges require immediate attention. Multiple discharges are usually not well tolerated and can be emotionally devastating to the patient from a psychological perspective.³⁸ Myocardial injury and transient reduction in left ventricular function can occur from multiple shocks. This has been associated with a poorer long-term prognosis. Multiple discharges can lead to premature depletion of the battery life.

ESTABLISHING THE ETIOLOGY

It is important to establish the etiology of the shocks to administer proper and prompt management (Table 46-2). Determine whether the shocks are appropriate for ventricular tachycardia or fibrillation, inappropriate therapy, or phantom shocks.⁴⁴ More than one-third of patients with a history of ventricular tachycardia or ventricular fibrillation receive a shock within 2 years of the ICD implantation.⁴⁵ Recurrent ventricular tachyarrhythmia is a common cause of repeated ICD firing. Ineffective termination of a tachyarrhythmia can be the result of an increase in defibrillation thresholds secondary to concomitant antiarrhythmic drug therapy and lead migration or lead dislodgement. Inefficient termination can occur if inappropriately low amounts of energy are programmed for the initially administered shock. Shocks may be the result of inappropriate detection of supraventricular tachycardias (SVTs), most frequently sinus tachycardia and atrial fibrillation.⁴⁶ The administration of a low-energy shock may convert a benign SVT into an unstable ventricular arrhythmia, resulting in an ICD proarrhythmia. The introduction of an atrial lead in dual-chamber devices has aided in the discrimination process between SVTs and ventricular tachyarrhythmias. Rapid SVTs are particularly a problem in children and athletic individuals in whom exercise or reductions in medications that slow heart rate (e.g., beta-blockers) are commonly encountered causes of inadequate shocks from sinus or supraventricular tachycardia. Inappropriate ICD firing can occur because of the erroneous detection of noise or interference that can be the result of insulation breakdown or a loose set screw (Figure 46-9). Oversensing of T waves, pacing artifacts, R waves, and electromagnetic interference may lead to inappropriate detection and discharge. Patients who have received painful shocks occasionally suffer from phantom shocks (i.e., the perception of a shock in the absence of any arrhythmia or therapy from the ICD).⁴⁴ Consider random component failure if all other causes have been ruled out.

TABLE 46-2 Causes of Frequent ICD Discharges	
Appropriate	
Nonsustained ventricular tachyarrhythmias	
Sustained ventricular tachyarrhythmias	
One shock needed to terminate each episode of sustained ventricular tachyarrhythmia	
Recurring episodes, each one terminated by a shock	
Inappropriate	
Increase in defibrillation thresholds (antiarrhythmic drug therapy)	
Oversensing of signals	
Double and triple counting of pacing artifacts	
Electromagnetic interference	
Environmental electrical noise	
P-wave oversensing	
Sensing lead failure (migration or dislodgement)	
T-wave oversensing	
Phantom (absence of both arrhythmia and ICD discharge)	
Random component failure	
Supraventricular tachyarrhythmia that satisfies detection criteria	
Atrial fibrillation	
Paroxysmal supraventricular tachycardia	
Sinus tachycardia	

FIGURE 46-9. Inappropriate ICD discharge. Intracardiac electrogram of a patient with a Ventak Mini III presenting with repetitive ICD discharges. Examination of the intracardiac electrograms (line 2) demonstrates noise sensed as ventricular fibrillation (VF) resulting in an inappropriate shock (CD). Noise was traced to an insulation break in the ICD lead. Lead replacement corrected the problem.

APPROACH TO THE PATIENT WITH MULTIPLE ICD DISCHARGES

These patients must be under constant ECG monitoring. Apply defibrillator pads in anticipation of the development of an unstable cardiac arrhythmia. This may be the only means of establishing a shock-rhythm correlation in devices with limited stored diagnostic capabilities. Sedation is reasonable in extremely anxious patients. Obtain an Electrophysiology consultation for assistance in interrogating the ICD. The device should be interrogated and stored electrograms obtained for analysis.⁴⁷ It is often useful to inquire about the pattern of ICD discharge. Consecutive shocks occurring within a few seconds suggest an inappropriate discharge for SVT, oversensing, or device failure. Isolated shocks occurring every few minutes may be indicative of recurrent ventricular tachycardia. Progressive dyspnea on exertion, shortness of breath, orthopnea, or paroxysmal nocturnal dyspnea suggests new-onset or worsening heart failure, which can precipitate ventricular arrhythmias. Potential reversible causes (e.g., electrolyte abnormalities) need to be identified and promptly corrected.

Careful examination of the 12-lead ECG is crucial. ST-segment changes may imply an acute coronary syndrome and determine the need for primary intervention or thrombolytic therapy. An ECG obtained during an actual shock may establish whether the culprit arrhythmia is a supraventricular or ventricular tachycardia.

Emergently deactivate the ICD if the discharges are inappropriate. Causes of inappropriate shocks include SVT and misinterpretation of complexes (e.g., premature ventricular contractions and T waves) as dysrhythmias. Manage supraventricular tachyarrhythmias with intravenous drug therapy (e.g., adenosine, diltiazem, or verapamil). Make attempts to control the patient's ventricular response in the situation where discharges are secondary to rapid atrial fibrillation with atrioventricular (AV) nodal blocking agents (e.g., beta-blockers, digoxin, diltiazem, verapamil). Attempt chemical cardioversion or electrical cardioversion in the event of hemodynamic instability. Shocks secondary to prolonged episodes of nonsustained ventricular tachycardia can be prevented by adjusting initial detection parameters coupled with the addition of antiarrhythmic drug therapy.

Patients with an ICD can develop "electrical storm." **Patients in electrical storm require immediate attention.** This condition involves recurrent, hemodynamically unstable ventricular tachycardia or fibrillation occurring two or more times in a 24-hour period.⁴⁸ Potential triggers can be found in approximately 66% of patients and include new or worsened heart failure, changes in antiarrhythmic medication, psychological stress, and hypokalemia. Electrical storm consists of monomorphic ventricular tachycardia in most patients

and indicates the presence of a reentry mechanism. Ventricular fibrillation is rare and may be indicative of acute ischemia. The key intervention in electrical storm is reduction of the elevated sympathetic tone by intravenous beta-blockers, benzodiazepines, and amiodarone.⁴⁹

Consult an Electrophysiologist promptly and stabilize the patient prior to transfer to the Intensive Care Unit (ICU). Apply defibrillator pads in anticipation of the development of unstable cardiac arrhythmias. **Potential reversible causes (e.g., electrolyte abnormalities) need to be identified and promptly corrected.** The treatment of choice is magnesium and/or temporary cardiac pacing if torsades de pointes is diagnosed. Thrombolysis or urgent catheterization with intervention may be needed in the setting of an acute myocardial infarction. Deactivate the ICD if analysis of stored electrograms demonstrates ineffective discharges. Attempts to terminate the arrhythmia in the hemodynamically stable patient via ATP is a useful option. Intravenous antiarrhythmic drugs are a necessary adjunct in these situations. The administration of amiodarone in combination with beta-blocker therapy has been shown to be successful in the management of electrical storm.⁵⁰ A combination of antiarrhythmic drugs will often be required.

ICDs AND CARDIAC RESUSCITATION

Manage patients with an ongoing arrhythmia by ACLS guidelines regardless of the presence of an ICD. Although in the most instances ICD function will be found to be appropriate, this cannot be assumed.²⁷ Follow ACLS guidelines and consider the device inactive.^{51,52} Deactivate the device if the clinical situation permits and an ICD programmer is readily available. This will prevent the reinduction of ventricular fibrillation or tachycardia due to concomitant ICD discharges that may occur during cardiopulmonary resuscitation (CPR). **There is often some hesitation to initiate resuscitative measures in patients with an ICD for fear of getting shocked. This fear is understandable but unwarranted. A mild electric shock might be perceived. These discharges do not pose a risk to persons administering CPR nor do they damage external monitoring devices.**

External defibrillation is permissible. The paddles or pads should be positioned away from the device. Individuals with epicardial patches may require higher energies for defibrillation. Current can be shunted from the myocardium through the patches. The insulated portion of the patch serves as a shield from the administered shock. An anteroposterior paddle configuration has been suggested in patients with epicardial patches for changing the defibrillation vector.⁵³

The ICD may be reset after external defibrillation is delivered, especially if the paddles or pads are in proximity to the generator. It is important that devices be reinterrogated after the successful completion of a resuscitation to ensure that programmed parameters have not been altered.

INFECTION OF AN ICD

Technologic advances have made a gradual reduction in the size of the pulse generator possible. This small size permits superficial implantation of the pulse generator in the anterior chest wall.⁵⁴ The ICD implantation technique is similar to pacemaker implantation. ICD infections can involve the generator pocket, the leads, or both. Infection is more likely after a recent generator replacement.^{55,56} **An infected ICD system represents a serious medical situation that should be dealt with urgently (Figure 46-7).** The diagnosis of an ICD infection is based on finding infection in the pocket site (e.g., drainage, pain, redness, swelling, or ulceration).

In the past, the incidence of infection ranged from 2% to 11% in systems that were implanted via thoracotomy or sternotomy.⁵⁷ The infection rates for nonthoracotomy implants approach those of pacemakers and range from 0.8% to 1.5%.^{55,57-60} Infections generally present clinically within 6 months of the implant, but more typically within the first 3 months. Suspect an infection when local and systemic signs and symptoms of inflammation or a skin erosion are apparent (Figure 46-7).⁶¹ Prompt referral to a specialist is warranted. Removal of the device and leads is required in almost all cases. Endocarditis prophylaxis with antibiotics is not generally warranted.

Systemic symptoms are seen in up to 50% of patients, especially in those with infections caused by *Staphylococcus aureus*.⁶² The pocket and/or incision site is often visibly erythematous, warm, and tender. A fever may be present. Blood work often reveals a leukocytosis. Frank suppuration or device erosion may be seen. Pericarditis may be evident if epicardial patches are infected. Blood cultures may aid in documenting the culprit organism. Infections occurring late are generally indolent and rarely present with fever or leukocytosis, and blood cultures are generally negative.

The most common microorganisms in 50% of infections include *S. aureus* and coagulase-negative staphylococci.⁵⁶ Other common organisms include *Escherichia coli*, *Pseudomonas*, *Serratia*, *Corynebacterium*, *Propionibacterium acnes*, *Candida* species, streptococci, and atypical mycobacteria.⁶³ Infection is generally the result of skin contamination during implantation of the ICD. It can also occur due to hematogenous seeding from distant intravenous sites, indwelling catheters, or concomitant infections (e.g., respiratory or urinary tract). A hematoma in the pocket increases the infection risk.^{64,65}

The TYRX Absorbable Antibiotic Envelope (Medtronic, Minneapolis, MN) was approved for use by the FDA in 2014. It is an envelope that covers the ICD before it is implanted. It releases rifampin and minocycline to prevent infection at the implantation site. The envelope starts to dissolve in 1 month and is dissolved between 2 and 3 months of implantation. It may be impossible to tell an infection from an allergic reaction to the contents of the envelope.

APPROACH TO AN INFECTED ICD

The goals of therapy include identifying the culprit organisms, establishing the extent of the infection, and containment of the infection.⁵⁶ **Consider endocarditis in the differential of all patients with an ICD and a fever.** Obtain routine laboratory tests, including a complete blood count and differential. Draw blood for cultures. It must be kept in mind that blood cultures are often negative. Wound cultures and Gram stains may be helpful in differentiating an infection

from a pocket hematoma, sterile subcutaneous fluid accumulation, or an inflammatory reaction to pacemaker components. **Attempts to aspirate the pocket should be performed only in consultation with an Electrophysiologist and/or Surgeon. A sterile pocket or hematoma can often become infected after an aspiration.**

There is no single diagnostic modality that can determine the extent of the infection. ICD infections should never be assumed to be localized, as organisms can migrate from the leads into the heart. A chest radiograph may reveal patch deformities or wrinkling, suggesting distal migration of the infection. A computed tomography (CT) scan can detect localized fluid accumulation and patch wrinkling. **Transesophageal echocardiography (TEE) has been the method of choice to confirm the presence of vegetations on the leads or coil.** Intracardiac echocardiography (ICE) has shown accuracy as a diagnostic tool.

A few reports suggest that infection of a defibrillator system may be controlled. The treatment of choice continues to be removing the entire system followed by the administration of parenteral antibiotic agents.⁶⁶ Some localized infections restricted to the ICD generator have been managed with the removal of the generator, debridement, and systemic antibiotic therapy. Vancomycin is frequently used as an empiric agent when cultures are still pending given its good coverage against coagulase-negative staphylococci and methicillin-resistant *S. aureus* (MRSA). Empiric gram-negative and fungal coverage may be necessary in the immunocompromised patient.

ELECTROMAGNETIC INTERFERENCE AND ICDs

The ability of ICDs to function is dependent on their ability to sense intrinsic cardiac electrical activity. Hermetic shielding, filtering, interference rejection circuits, and bipolar sensing have safeguarded ICDs against the effects of common electromagnetic sources. Exposure to EMI may still result in oversensing, asynchronous pacing, ventricular inhibition, and spurious ICD discharges. EMI may lead to loss of output, increased pacing thresholds, and decreased R-wave amplitude. Common sources of EMI include cellular phones, electronic article surveillance (i.e., antitheft) devices, and metal detectors. Issues only arise with prolonged exposure. Patients are advised to use the opposite ear when using a cell phone and not stay near antitheft devices or metal detectors long. Occupational sources of EMI include high-voltage power lines, electrical transformers, arc welding, and electric motors. EMI can be encountered through medical equipment and procedures (e.g., magnetic resonance imaging, electrocautery, spinal cord stimulators, transcutaneous electric nerve stimulator units, radiofrequency catheter ablation, therapeutic diathermy, and lithotripsy).^{67,68} It appears that some spinal cord stimulators may not cause EMI.⁶⁹

Instruct patients with ICDs and pacemakers to avoid environments with large magnetic fields. Extremely low-frequency electromagnetic fields in daily life do not interfere with ICD sensing.^{70,71} Strong electromagnetic fields of 50 Hz or greater in some occupational environments can cause inappropriate sensing and may lead to false detection of arrhythmias and a shock to the patient. The use of cellular phones is permissible. The FDA recommends avoiding direct contact of the phone with the ICD. Use the contralateral ear while using the phone. Inappropriate shocks have been documented through electronic article surveillance systems. Studies have deemed it safe for patients to walk through these systems if they avoid lingering around these devices. New concerns have been raised regarding household appliances. Patients can be reassured that EMI is unlikely to affect their ICDs if induction ovens are used in their kitchens.⁷²

FIGURE 46-10. Comparison of the subcutaneous ICD with the transvenous ICD. (Photo used with permission from reference 74.)

The strong magnetic fields of magnetic resonance imaging (MRI) machines can interfere with ICD functioning. They can induce electrical current flow in the ICD lead that can initiate an arrhythmia or be sensed as an arrhythmia and precipitate spurious therapies. Patients with an ICD should not be placed in an MRI field without special cardiac monitoring. Newer technology has led to development of some MRI-compatible ICDs (e.g., Biotronic, Boston Scientific, and Medtronic). There is no such problem with fluoroscopy, CT scanning, or nuclear-based imaging.

SUBCUTANEOUS ICD TECHNOLOGY

There are constant improvements being made in ICD technology. Minimally invasive and entirely subcutaneous ICDs (S-ICD) have been developed (**Figures 46-10 and 46-11**).⁷³⁻⁷⁵ The advantages include that it has a simplified implantation procedure, it does not require vascular access or intracardiac leads, no imaging or fluoroscopy equipment is required, and the device may be as effective as current ICD systems.⁷⁶ Potential complications (e.g., deep venous thrombosis, intracardiac thromboses, tricuspid valve disease, or complications related to central venous access) can be eliminated.

FIGURE 46-11. Chest radiograph of a subcutaneous defibrillator. (Photo used with permission from reference 73.)

The electrode is implanted parasternally, and the ICD generator is implanted on the anterolateral chest wall (**Figures 46-10 and 46-11**). This system can effectively treat ventricular fibrillation.⁷⁶ The Emergency Department evaluation of the S-ICD is the same as the transvenously placed ICD.

WEARABLE ICD TECHNOLOGY

A patient may present to the Emergency Department with a wearable ICD (Zoll Medical Corp., Pittsburgh, PA). These are composed of the defibrillator vest, the wearable computer/monitor/power source, the battery charger, and the blue tooth transmitting unit that transmits to the manufacturer for monitoring the rhythms (**Figure 46-12**). The unit talks, vibrates, and warns the patient of an impending shock. The monitor has a display screen. A rechargeable battery snaps into the monitor. Removal of the battery inactivates the device. The wearable ICD is approximately \$4000 per month, a

FIGURE 46-12. The wearable defibrillator. **A.** The components include the portable computer/monitor/power source (1), the wearable vest (2), the charger and Bluetooth transmitter (3), and the wearable case for the around the neck or waist (4). **B.** The vest (1), electrode belt or defibrillator (2), heart sensors (3), monitor connection cable (4), vibration box (5), and defibrillator therapy pads (6). **C.** The loaded electrode belt. (Photos courtesy of Zoll Medical.)

FIGURE 46-12. (Continued)

cost significantly lower than that of an ICD. It can be used to bridge the time between diagnosis and ICD placement.

The patient may experience a shock and come to the Emergency Department. Remove the battery pack to inactivate the device. Remove the vest with the defibrillator unit from the patient. Apply defibrillator pads/patches to the patient and attach these to the machine. Call a field engineer to interrogate the device or the manufacturer.

TWIDDLER SYNDROME

Twiddler Syndrome can be seen with any implantable subcutaneous device. Patients manipulate the device intentionally or unintentionally. This moves the ICD within the subcutaneous pocket, curling the leads (Figure 46-13).⁷⁷ The leads can be displaced from the ICD, displaced from the heart, or fracture. This can result in syncope or pacing of structures if the device is providing impulses to other structures (e.g., abdominal muscle wall spasm, arm spasm, chest wall, diaphragm spasm, and hiccups). The device can demonstrate problems associated with lead displacement or fracture. The device needs to be fixed by the specialist who inserted it. They will replace the lead(s), reposition the lead(s), and secure the ICD in the pocket.

FIGURE 46-13. Chest radiograph of a patient with Twiddler syndrome. (Photo used with permission from reference 77.)

SUMMARY

Expanding clinical indications, advanced new technology, and the increasing number of annual implants require Emergency Physicians to become familiar with problems typically encountered by the patient with an ICD. Complications associated with ICDs are not uncommon. Troubleshooting and programming should be performed in conjunction with consulting an Electrophysiologist. Patients presenting with cardiopulmonary arrest may require the device to be deactivated and external defibrillation performed. Do not apply external defibrillation paddles directly over the ICD.

Left Ventricular Assist Device (LVAD) Assessment

Paulino Alvarez, Myles McClelland, and Ashrith Guha

INTRODUCTION

Heart failure affects more than 5 million Americans, of whom approximately 6% have advanced heart failure.^{1,2} Advanced heart failure is characterized by severe progressive symptoms despite optimal medical therapy, recurrent hospital admissions, and very poor prognoses. Therapeutic options include cardiac transplantation, mechanical circulatory support, and palliative care. Cardiac transplantation is limited by donor availability and recipient eligibility.^{3,4}

Left ventricular assist devices (LVADs) provide mechanical circulatory support. They are pumps that move blood from the left ventricle to the aorta. LVADs were first approved in the mid-1990s to support patients as a bridge to transplant (BTT) until a suitable donor heart became available. They have advanced in recent years as a superior alternative to medical therapy in patients who are not eligible for transplantation (i.e., destination therapy [DT]).⁵ Strict criteria have been established and must be met for a patient to be considered a candidate for a LVAD as DT (Table 47-1).⁶

The introduction of smaller rotatory, continuous-flow, durable intracorporeal pumps has led to an exponential increase in the number of implants. More than 10,000 continuous-flow LVADs (CF-LVADs) have been implanted in the United States.^{7,8} The 1-year

TABLE 47-1 Indications for an LVAD

Balloon pump dependent for 7 days
Failure to respond to optimal medical management for at least 45 of the last 60 days
IV inotrope dependent for 14 days
Left ventricular ejection fraction < 25%
New York Heart Association functional class IV
Not a heart transplant candidate
Severe functional limitation with a peak $\dot{V}O_2 \leq 14$ mL/kg/min

survival after CF-LVAD implantation for DT has been reported to be approximately 80%.⁹ The complication rates are high. Within 1 year of implantation, approximately 80% of patients are readmitted for LVAD-associated causes (e.g., device infection, device malfunction, or management of nontherapeutic anticoagulation) and non-LVAD-associated causes (e.g., infections, progressive right ventricular failure, psychosocial issues).^{10,11} This significant morbidity, along with the increasing number of patients supported by LVADs, requires that Emergency Physicians understand the function and complications of LVADs.¹²⁻¹⁴

LVAD DEVICES

PUMP FUNDAMENTALS

The LVAD can be conceptualized as a pump that uses energy to move fluid from one site to another (Figures 47-1 and 47-2).¹⁵ LVADs have an inflow cannula (i.e., suction pipe) in the left ventricle, a pump, an outflow cannula (i.e., discharge pipe) in the ascending aorta, and a driveline that connects the pump with the system controller. The system controller is connected to a power source (i.e., batteries or direct power). Continuous-flow pumps can be divided into axial and centrifugal. An axial pump uses a propeller in a pipe and transmits rotational energy without a change in the direction of blood. A centrifugal pump uses an impeller and pushes the blood and directs it tangentially. These mechanisms have a fundamentally different hydrodynamic performance.¹⁶

The pressure difference across the inlet and outlet of the pump is known as the head pressure. The head pressure of an LVAD varies during the cardiac cycle, increasing during diastole and decreasing during systole. The head pump curves describe the relationship of head pressure on the y-axis and pump flow on the x-axis at the defined operating speed (Figure 47-3).¹⁷ There is an inverse relationship between head pressure and flow. The pump speed is fixed. When the head pressure increases, most of the rotational energy transmitted by the pump is “wasted” generating pressure. When the head pressure decreases, the rotational energy is used to generate flow.

Centrifugal flow devices have “flat” head pump curves (Figure 47-3). This means that small variations in head pump pressures are associated with large variations in flow. Axial flow pumps have a steep head pump curve (Figure 47-3). They show smaller variation of flow with similar reductions in head pressure. The clinical significance of this hydrodynamic behavior is increased flow pulsatility and afterload sensitivity in patients with centrifugal pumps.¹⁷ Axial pumps show high pressure differentials and power consumption at lower flow rates. The pump pulls harder at lower flow rates. In the context of relative or absolute hypovolemia, the patient is more likely to suffer suction phenomena or the contact of the inflow cannula and the left ventricular endocardium.

This chapter will focus on two specific devices (Figure 47-1). The Heart Mate II (Thoratec Corp., Pleasanton, CA) was approved for BTT and DT. It is a second-generation preperitoneal axial pump

FIGURE 47-1. Two types of LVADs. **A.** A compact centrifugal-flow device with an integrated inflow cannula designed for intrapericardial placement. The device incorporates a bearing-less design with magnetic and hydrodynamic levitation of the internal impeller. **B.** An axial-flow device that requires bearing support of the internal impeller and is implanted outside the pericardium in a preperitoneal (pump) pocket. (Used with permission from reference 15.)

with a titanium propeller supported by mechanical bearings that can rotate between 6000 and 15,000 revolutions per minute (rpm). The typical speed is 8800 to 9200 rpm. The HeartWare HVAD (HeartWare, Framingham, MA) is only approved for BTT (**Figures 47-1**

and 47-4). It is a third-generation small intrapericardial centrifugal pump. The impeller is supported by hydrodynamic and magnetic mechanisms that are friction free. It can rotate at a speed range between 1800 and 4000 rpm. The typical speed is 2600 to 2900 rpm.

FIGURE 47-2. An example of a patient with the components of an LVAD. (Courtesy of Thoratec Corp.)

SYSTEM CONTROLLER

The system controller is a small computer that regulates LVAD function (**Figure 47-4C**). It serves as a user interface by displaying advisory alarms, battery status, flow, hazard alarms, power, pulsatility parameters, and speed. Pump speed is measured in rpm and is the only variable that can be programmed by the operator. Pump power is a direct measure of the energy consumption by the pump. Flow is not directly measured in these pumps using a flow meter. LVAD flow is estimated using power in the Heart Mate. LVAD flow is estimated by using hematocrit, pump speed, and power in the HeartWare. Trends in flow are clinically useful, but absolute values do not accurately represent the cardiac output. The increase in intracavitary pressure during ventricular systole causes a decrease in total head pressure with a consequent increase in flow.

This variation in flow during the cardiac cycle represents the pulsatility. Pulsatility depends on the function of the left ventricle as a pump and preload. Pump flow pulsatility is the difference between the minimum (i.e., trough) and maximum flows. The Heart Mate pulsatility index (PI) represents the delta flow/average flow over 15 seconds. Values range between 1 and 10. The higher the PI, the less LVAD support. PI event occurs when there is a 45% change in flow from the previous 15-second running average. The pulsatility of the HeartWare is displayed in the pump flow waveform.

ANTICOAGULATION

Current LVADs have demonstrated acceptable hemocompatibility. Warfarin anticoagulation with international normalized ratio (INR) values of 2 to 3 and antiaggregation with 81 to 325 mg of aspirin daily remain the standard of care.

OTHER CARDIAC FACTORS INFLUENCING LVAD FUNCTIONS

LVADs provide left ventricular unloading. Several patient conditions may influence LVAD efficiency. The degree of left ventricular dysfunction, preexisting right ventricular dysfunction, and progressive right ventricular dysfunction may contribute to the appearance of a low-flow state and congestion. Aortic insufficiency may lead to ineffective cardiac output and heart failure symptomatology. The patient is subject to right to left shunting in the context of low left-sided filling pressures with an untreated patent foramen ovale.

EVALUATION OF THE LVAD PATIENT

Patients with LVADs are subject to the same clinic conditions as any member of the population (**Figure 47-5**).¹⁸ **Do not anchor on the LVAD as the cause of the complaint. Treat the appropriate pathology while being sensitive to the alterations in the patient's physiology and increased risks secondary to the LVAD.** There are some common clinical scenarios leading to Emergency Department evaluation of LVAD patients. The patient may have no symptoms, but the device is alarming. The patient may be symptomatic (e.g., chills, fatigue, fever, gastrointestinal bleeding, neurologic deficits, and shortness of breath) with or without the LVAD alarming. The patient may present unconscious with or without signs of circulatory collapse and with or without the LVAD alarming.

LVAD implantation occurs after a careful multidisciplinary team evaluation of cardiac (e.g., arrhythmias, ischemic heart disease, right ventricular function, and valvular heart disease) and noncardiac (e.g., hepatic, neurologic, and pulmonary function, psychosocial factors, renal factors) considerations. All certified ventricular assist device centers have LVAD coordinators that play a central role in the longitudinal follow-up of these patients. **Obtain contact information from the implanting center and the patient's LVAD coordinator as early as possible to help facilitate care.** A list of high-yield questions is provided in **Table 47-2**.

PHYSICAL EXAMINATION OF THE LVAD PATIENT

Approximately 60% of patients with current CF-LVADs do not have a palpable pulse. A manual cuff can be used to measure blood pressure (BP) when a radial pulse is readily palpable. Record the mean BP if the systolic blood pressure (SBP) and diastolic blood pressure (DBP) are attainable. The mean BP can be defined as $[DBP + (SBP - DBP) \div 3]$. Consider the use of a Terumo BP cuff. The Doppler technique can be used in case of failure to obtain BP recordings. The opening Doppler BP is used as the SBP.¹⁹ Place an arterial line (Chapter 72) in critically ill patients in whom manual or Doppler BP measurement is technically difficult or unreliable or continuous pressure measurement is needed to help guide care.

The use of Doppler is indicated when the radial pulse is not palpable. Place the manual BP cuff following standard recommendations of size and location. Place the Doppler probe over the brachial artery and auscultate the brachial pulse. Inflate the cuff until the pulse is no longer audible by Doppler. Slowly deflate the cuff in 2 to 3 mmHg/sec increments, allowing the reestablishment of flow. Record the opening pressure when the pulse becomes audible. The opening pressure will closely estimate the mean BP. The mean BP goal in patients supported by CF-LVADs should be approximately 70 to 90 mmHg.

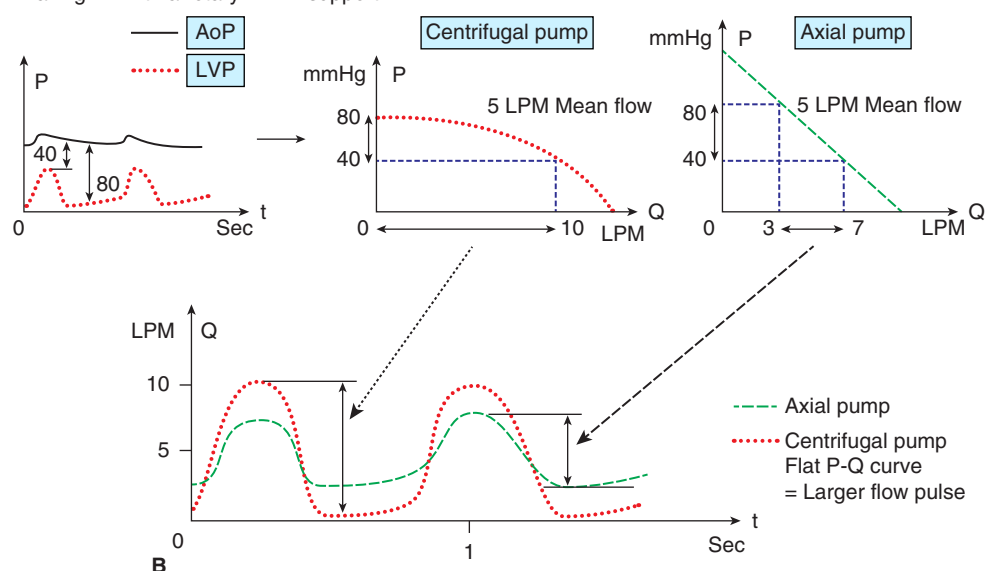

Examine the patient and the LVAD. **Pulse oximetry may not be reliable in nonpulsatile flow states. Perform arterial blood gasses if there is a question of adequate oxygenation.** Direct the chest auscultation to detect the continuous hum characteristic of

a working CF-LVAD. Focus the physical examination on detecting congestion, hypoperfusion, and neurologic deficits. Carefully evaluate the driveline integrity.²⁰ **Do not pull on the driveline.** Evaluate the driveline exit site to assess for signs of inflammation or infection (e.g., drainage, induration, pain, or redness). Evaluate the system controller for signs of burns, deterioration, immersion, or other signs of wearing. Evaluate any LVAD alarms as described below.

ANCILLARY TESTS

Chest radiographs can be useful (**Figure 47-6**).¹⁸ They can detect causes of dyspnea or fever (e.g., cardiomegaly, infiltrates, pericardial effusions, or pleural effusions). Gross malalignment of the inflow cannula can be observed in chest radiographs. Consider a Panorex radiograph to rule out a dental infection. Electrocardiogram evaluation may disclose atrial fibrillation, which has been associated with an increased risk of ischemic stroke and ventricular tachycardia in patients who present with nonspecific symptoms.

Focused laboratory evaluation may provide useful information. A complete blood count (CBC) can be used to determine acute anemia

from bleeding or hemolysis. Thrombocytopenia can be related to platelet consumption. Leukocytosis is associated with an infection. Evaluate the driveline and look for signs of septic embolism. Lactate dehydrogenase (LDH) is increased in hemolysis that may be related to pump thrombosis. Low-grade elevation of LDH is frequently seen in LVAD patients. Therapeutic anticoagulation evaluation looks at the INR for patients using warfarin. Consider pump thrombosis with a low INR, high LDH, and power spikes. Renal function increases in renal failure from hypoperfusion and/or renal congestion due to right ventricular failure. Liver function test alterations may be a clue to right ventricular failure. Brain natriuretic peptide (BNP) may be elevated in incomplete unloading pump thrombosis, left ventricular failure, or right ventricular failure.

Echocardiography provides essential information for the assessment of the LVAD patient. The parasternal long axis is useful to evaluate for aortic valve opening, left ventricular filling, left ventricular function, pericardial effusion, and right ventricle function. M-mode is used to characterize the timing of atrioventricular valve opening. Color Doppler may be useful to assess for the presence of aortic insufficiency. Additional views will complement the evaluation of

TABLE 47-2 High-Yield Questions

Question	Possible etiology
Are you experiencing shortness of breath and/or leg swelling?	Left-sided heart failure Right-sided heart failure
Have you noticed the development of dark urine?	Acquired hemolysis Rotor pump thrombosis
Are you experiencing fatigue?	Acute blood loss Gastrointestinal bleeding Heart failure Hemolytic anemia
Have you experienced darker and/or bloody stools?	Acquired arteriovenous malformations Gastrointestinal bleeding
Have you noticed drainage and/or pain around your driveline exit site?	LVAD-related infection
Have you experienced fever and/or chills?	LVAD-related infection
Have you experienced any alarms? If so, what kind (e.g., advisory or hazard)?	Driveline malfunction Hypovolemia Pump thrombosis Driveline fracture
Have you had any incidence of trauma to driveline?	

ventricular function and provide information on the inflow cannula position. The inflow cannula position is considered normal when aligned with the left ventricle inflow tract. Algorithms for the evaluation of left ventricle filling pressures and detailed guidelines for echocardiographic evaluation have previously been published and are beyond the scope of the Emergency Physician. A ramp test (i.e., changes in left ventricle diameter and atrioventricular valve opening are measured with progressive LVAD speed changes) should only be performed in experienced centers. Suspect incomplete unloading if the left ventricle is dilated and the atrioventricular valve is opening.

LVAD INTERROGATION

Evaluate the system controller and patient for evidence of device function.²⁰ Identify any alarms (Table 47-3). Verify all connections and that the batteries are charged. Analyze alarms in the clinical context of the patient (Table 47-3). Suspect a short to shield phenomenon when low-flow alarms or pump stoppage occurs when the device is connected to the power base unit and resolves when it is

TABLE 47-3 Some of the More Common Alarms on an LVAD Controller

Alarm	Cause	Actions
LVAD stopped; read heart flashing	Battery depletion Controller malfunction Driveline disconnection	Connect batteries Connect driveline Replace batteries Replace controller Hold vasodilators Treat sepsis
High flow	Increased atrioventricular opening Moderate to severe mitral regurgitation Sepsis Vasodilation	
Low flow	Arrhythmias Bleeding Decreased atrioventricular opening Hypovolemia Kinking or obstruction of tubing Pericardial effusion/tamponade Right ventricular dysfunction Right ventricular enlargement	Bolus fluids Relieve kinking of tubing Relieve obstruction of tubing Relieve pericardial effusion Relieve pericardial tamponade Transfuse and stop bleeding Treat arrhythmia Treat increased systemic resistance
High power	Pump thrombosis	Contact implanting center IV anticoagulation if INR is < 2
High pulsatility index; increased pulsatility waveform	Recovery of left ventricle function Percutaneous lead damage	Look for evidence of recovery Assess LVAD components
Low pulsatility index	Excessive pump speed Hypovolemia Poor native ventricular function	Add inotropic support Adjust pump speed Fluid bolus
Suction event*	Arrhythmias Cannula opening obstruction Excessive ventricular unloading Hypovolemia Kinking or obstruction of tubing	Fluid bolus Lower pump speed Relieve cannula obstruction Relieve kinking of tubing Relieve obstruction of tubing Treat arrhythmias

*May manifest as alarms, low flows, or low pulsatility index. Pulsatility index events occur when there is a 45% +/- change from the previous 15 second running average.

connected to batteries. The Heart Mate device driveline consists of three pairs of cables covered by a metallic shield. The energy will be drained from the pump, causing a voltage drop and alarms if there is a loss of integrity to the wires and any wire contacts the metallic shield while the device is connected to a grounded wire on the power base unit.²¹

CLINICAL SCENARIOS AND COMPLICATIONS SEEN IN LVAD PATIENTS

The following section describes some common scenarios and complications for conditions that occur in LVAD patients. Some of the conditions are listed in **Table 47-4**.

ECHOCARDIOGRAPHY

The use of bedside ultrasonography can help determine the etiology of the patient's symptoms. A large right ventricle and a small left ventricle is seen in pulmonary hypertension, right heart strain, and right-sided myocardial infarctions. Correct any acidosis, correct hypoxemia, consider inotropes, and evaluate for a myocardial infarction. A small right ventricle suggests dehydration. Consider a fluid bolus. Enlarged right and left ventricles suggest pump failure or thrombosis. Small right and left ventricles suggest hypovolemia, gastrointestinal bleeds, and sepsis.

HEART FAILURE

The presence of signs and symptoms of heart failure warrants an evaluation. Look for LVAD-related and non-LVAD-related factors (**Figure 47-5**).^{22,23}

HYPERTENSION

Consider aggressive BP management (i.e., afterload reduction) with intravenous (IV) agents (e.g., nitroprusside) in the presence of signs

or symptoms of heart failure, low LVAD flows, and no evidence of neurologic deficits when the mean arterial pressure is > 110 mmHg. Consider the impact of the negative inotropic effects on the right ventricle before using IV beta-blockers.

HYPOTENSION

Patients with LVADs usually tolerate fluid boluses. Increase the preload with a fluid bolus. Consider the administration of inotropes for right ventricular failure (e.g., dobutamine) or sepsis (e.g., norepinephrine). Temporarily decrease the dosage of diuretics.

PUMP THROMBOSIS

An increase in early pump thrombosis has been reported in patients with CF-LVADs.²⁴⁻²⁶ The clinical presentation depends of the degree of pump dysfunction and residual intrinsic left ventricle function. It can range from mild fatigue to cardiogenic shock. Pump thrombosis leads to intravascular hemolysis manifesting in a significant increase in LDH and hemoglobinuria, which may be recognized by the patient as a change in the color of their urine. System controllers show power spikes and high estimated flows. Consider IV heparin anticoagulation and contact the LVAD reference center for further management support.²³ Routine thrombolytic administration is not currently recommended.²⁷

OTHER THROMBOTIC COMPLICATIONS

Aortic root thrombosis is caused by stagnant blood flow in the aortic root. Stasis of blood may lead to thrombus formation in the noncoronary cusp and may extend, causing obstruction of coronary arteries with subsequent ischemia. This may present as an acute coronary syndrome or ventricular tachycardia, or may embolize, causing ischemic complications (e.g., stroke). Consider a

TABLE 47-4 Diagnostic Characteristics of Common LVAD Complications

	Right ventricular failure	Pump thrombosis	Sepsis or infection	Hypovolemia
Symptoms	Congestion Shortness of breath	Dark urine Shortness of breath	Driveline site pain Fatigue Fever	Hematemesis Hematochezia Melena
Hemodynamics				
MAP	Decreased	Decreased	Decreased	Decreased
CVP	Increased	Increased	No change	Decreased
PCWP	No change	Increased	No change	Decreased
SvO ₂	Decreased	Decreased	Increased	Decreased
Physical examination	Edema Hepatomegaly JVD	Edema Rales	Cellulitis or purulent drainage from the drive-line	Decreased capillary refill Pale mucous membranes
Laboratory	Abnormal LFTs Increased BNP	Hemoglobinuria Increased BNP Increased free plasma hemoglobin Increased LDH May have INR < 2	Leukocytosis	Anemia Guaiac positive INR > 3
Echocardiography	Dilated right atrium or right ventricle	Dilated left atrium or left ventricle Aortic valve opening.	Normal	Underfilled
Device				
Power	Low	Increased	Increased	Decreased
Pulsatility	Low	Decreased	Increased	Decreased
Flow	Low	Increased	Increased	Decreased
Management	Consider RVAD Decreased LVAD speed Inotropes	Medical management: increasing antiplatelets and anticoagulation	IV fluids Stop vasodilators Treat infections	Blood transfusion IV fluids Treat bleeding

BNP, brain natriuretic peptide; CVP, central venous pressure; INR, international normalized ratio; JVD, jugular venous distension; LDH, lactate dehydrogenase; LFTs, liver function tests; LVAD, left ventricular assist device; MAP, mean arterial pressure; PCWP, pulmonary capillary wedge pressure; RVAD, right ventricular assist device.

computed tomography scan with IV contrast if this diagnosis is suspected.²⁸

Heart failure is a major risk factor for pulmonary embolism. Consider pulmonary embolism in patients who present with signs of acute right heart failure, especially if their INR is below the therapeutic range. Follow diagnostic and therapeutic guidelines for the treatment of a pulmonary embolism.²⁹

RIGHT VENTRICULAR FAILURE

Right ventricular failure is an important cause of morbidity and mortality in LVAD-supported patients.⁸ Factors related to the development of right ventricular failure include intrinsic baseline right ventricular function, right ventricular geometrical distortion due to displacement of the interventricular septum to the left, alterations of systolic and diastolic ventricular interdependence, and increased preload to the right ventricle.^{30,31} Treatment includes inotropes to augment right ventricular function (e.g., dobutamine, epinephrine, and milrinone), altering the pump speed, IV fluids, and vasopressors to maintain right ventricular perfusion pressure. Intubate the LVAD patient if necessary. Avoid elevated peripheral vascular resistance, high positive end-expiratory pressure, hypercarbia, and hypoxia, which worsen right ventricular function.

The Interagency Registry for Mechanically Assisted Circulatory Support (INTERMACS) defines right ventricular failure as signs and symptoms of persistent right ventricular dysfunction and central venous pressure > 18 mmHg with a cardiac index < 2.0 L/min/m². It is associated with the absence of elevated left atrial/pulmonary capillary wedge pressure > 18 mmHg, tamponade, ventricular arrhythmias, or pneumothorax. Right ventricular failure requires a right ventricle assist device implantation or inhaled nitric oxide or inotropic therapy for more than 1 week at any time after LVAD implantation. Right ventricular failure is severe if it requires a right ventricular assist device. It is moderate if IV inotropes or inhaled pulmonary vasodilators (e.g., inhaled nitrous oxide or prostaglandin E) are used. Right ventricular failure is considered mild if two of the following four criteria are met: central venous pressure > 18 mmHg or mean right atrial pressure > 18 mmHg, cardiac index < 2.3 L/min/m² using a pulmonary artery catheter, fluid overload (i.e., ascites or evidence of moderate to worse peripheral edema), or evidence of elevated central venous pressure by echocardiogram (i.e., dilated inferior vena cava without collapse) and in physical examination (i.e., signs of increased jugular venous pressure).

Right ventricular failure can be classified according to the timing of occurrence in relation to LVAD implantation as intraoperative, early (≤ 14 days), and late (> 14 days). Early right ventricular failure usually occurs in the implanting center. Late right ventricular failure may be more difficult to diagnose, and a high index of suspicion is important to avoid underdiagnoses. Right ventricular failure may manifest as progressive dyspnea, ventricular arrhythmias, or frequent hospitalizations.

SUCTION EVENTS

Suction or suck-down events are often due to hypovolemia where the intake cannula is against the wall of the ventricle (**Figure 47-7**). This can cause arrhythmias and syncope. The PI is reduced. Overcome this with IV fluid boluses and decreasing the pump rpms.

AORTIC INSUFFICIENCY

The development of aortic valve insufficiency in patients with a CF-LVAD may lead to incomplete left ventricular unloading and cardiac failure.^{25,32} It might be difficult to accurately quantify the degree of aortic valve insufficiency. The presence of heart failure

FIGURE 47-7. Ultrasound image of a suction event. LV, left ventricle. (Used with permission from reference 8.)

and continuous aortic valve insufficiency in M-mode color Doppler should raise the suspicion of aortic insufficiency.

ARRHYTHMIAS

Approximately 25% of LVAD patients will experience an episode of ventricular arrhythmia.^{8,25,33} The incidence of ventricular arrhythmias is higher in the first 30 days of implantation. The most important risk factor for late ventricular arrhythmias (i.e., > 30 days) is a history of preimplantation ventricular arrhythmias. The clinical presentation ranges from nonspecific symptoms to cardiovascular collapse. Factors that may impact the tolerance of ventricular arrhythmias include significant pulmonary hypertension with elevated pulmonary vascular resistance. Some have related the tolerance to ventricular arrhythmias to the capacity of withstanding Fontan circulation. Treatment of ventricular arrhythmias should follow standard advanced cardiac life support (ACLS) protocols, including cardioversion and defibrillation.³⁴

GASTROINTESTINAL BLEEDING

Approximately 30% of LVAD patients will develop gastrointestinal bleeding requiring at least 1 unit of red blood cell transfusion within 1 year after device implantation. Factors related to the increased gastrointestinal bleeding include therapeutic anticoagulation, platelet antiaggregation, continuous flow physiology that is related to acquired von Willebrand disease, and arteriovenous malformation in the gastrointestinal tract.^{8,25,33} **Arteriovenous malformations and gastritis are the most frequent causes of bleeding.** The patients frequently have recurrent episodes of gastrointestinal bleeding. It is important to inquire about current anticoagulation and antiplatelet regimens. The patient with recurrent gastrointestinal bleeding may have their anticoagulation discontinued.³⁵

The diagnostic and therapeutic approach is similar to that of other patients with gastrointestinal bleeding, but some additional considerations are needed. Have a low threshold for admission to the hospital given the presence of concomitant comorbidities. Aggressive anticoagulation reversal is discouraged given the high risk of thrombotic events in the absence of upper gastrointestinal bleeding with hematemesis or hemodynamic instability. **Comanagement with the LVAD reference center is crucial.** Transfuse leukocyte-reduced irradiated blood if possible to avoid allosensitization and cytomegalovirus in patients whom an LVAD was inserted as a BT. T.

No studies have assessed the safety of nasogastric tube placement. Nasal arteriovenous malformations are extremely common in this patient population. Epistaxis is not an uncommon complication.

STROKE

It has been estimated that approximately 17% of patients who receive an LVAD will suffer a stroke. Hemorrhagic strokes are just as common or more frequent than ischemic strokes.^{8,33,36} **Magnetic resonance imaging is contraindicated in LVAD patients.** The safety of thrombolytic therapy has not been studied. A history of bacteremia and device infection has been associated with increased risk of stroke.³⁷

INFECTIONS

Complications related to infection are the second most common cause of death 6 months after device implantation.^{8,25,33,38} The International Society of Heart and Lung Transplantation (ISHLT) classification of infections in LVAD patients is shown in Table 47-5.^{18,39} Pneumonia and sepsis are the most frequently reported complications, followed closely by percutaneous site infections. Percutaneous site infections affect 19% of the patients and are associated with increased mortality. **Careful inspection of the driveline insertion site for any evidence of cellulitis or drainage is mandatory.**²⁵ Initial investigation for a suspected infection includes a CBC, echocardiography, serial erythrocyte sedimentation rates,

and three sets of blood cultures over 24 hours.¹⁸ No standard guidelines for antibiotic therapy exist for this patient population.⁴⁰ Cover gram-negative organisms and methicillin-resistant *Staphylococcus aureus* (MRSA). Long-term use of an LVAD can result in reversible

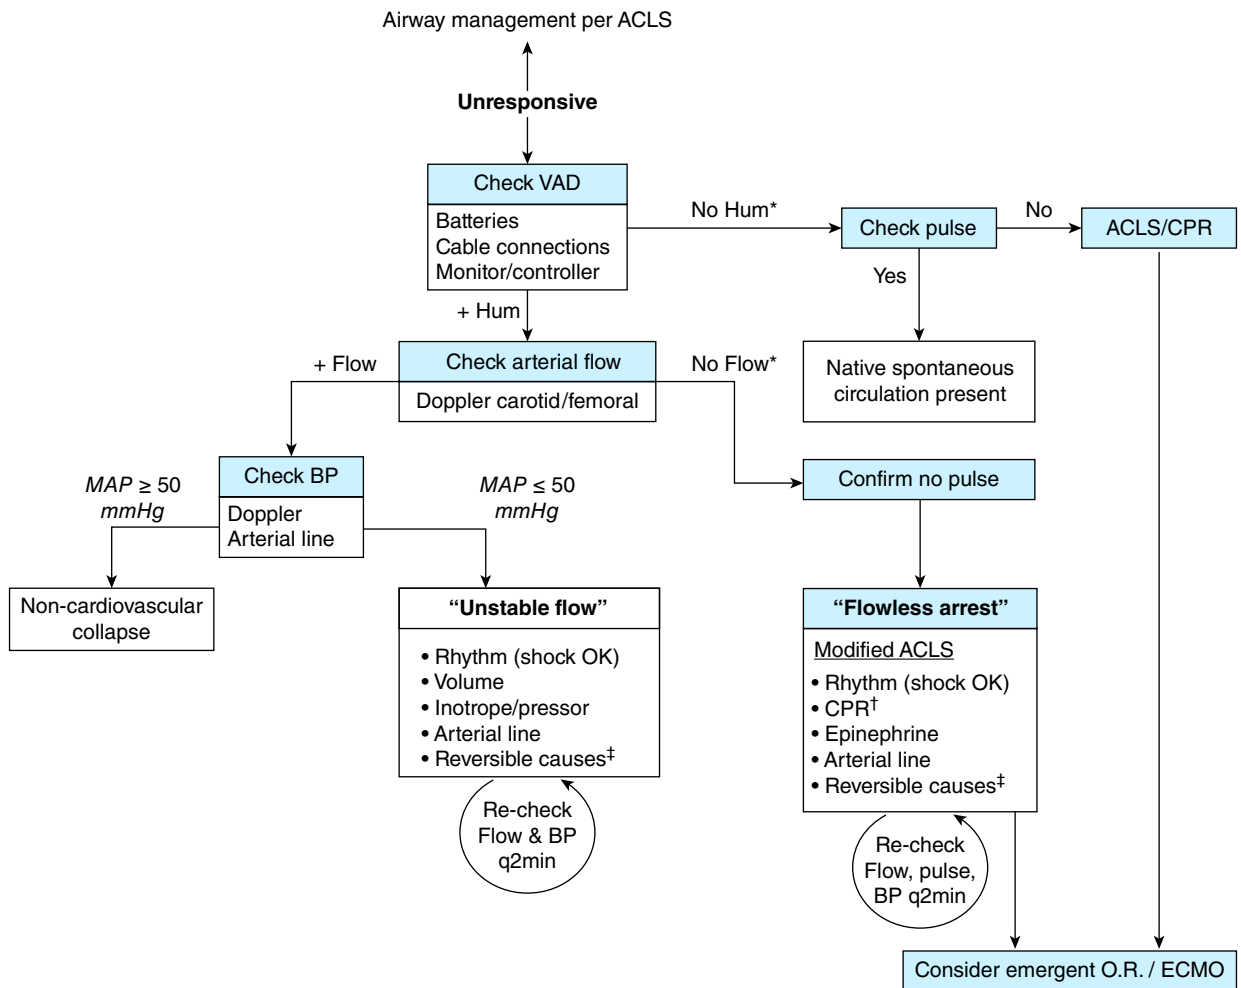

FIGURE 47-8. Management of cardiac arrest in the LVAD patient. ECMO, extracorporeal membrane oxygenation; MAP, mean arterial pressure. (Used with permission from reference 44.)

decreases in lung function.⁴¹ It can also result in decreased cardiac index,⁴² increased preload, increased afterload, increased pulmonary capillary wedge pressure, and a decrease in the ratio of right atrial pressure to pulmonary capillary wedge pressure.

CARDIAC ARREST

Patients with LVADs are not included in the special circumstances of resuscitation in the ACLS guidelines.⁴³ Airway management does not differ from other patients. **The assessment of circulation is significantly different. Most LVAD patients do not have a pulse.** Check the device controller and evaluate rapidly reversible causes of LVAD dysfunction (e.g., connect driveline and change batteries to connect to current). Evaluate the presence of the LVAD “hum” and native pulse.⁴⁴ There has been concern that cardiopulmonary resuscitation (CPR) may lead to outflow cannula displacement. This should not represent a contraindication to CPR but rather an additional reason for careful LVAD function evaluation.⁴⁵ Only perform CPR if the LVAD pump is not working and the patient has no BP or a low BP (i.e., < 60 mmHg).⁴⁶⁻⁴⁹ Rapid placement of an arterial line for invasive arterial BP monitoring is extremely useful to guide resuscitative efforts. A comprehensive algorithm is noted in **Figure 47-8**.

SUMMARY

Make a rapid attempt to communicate with the LVAD reference center team if the patient is clinically stable. Knowing how to evaluate LVAD parameters, the common complications surrounding LVADs, and the common device-related and device-associated complications is important to expedite the assessment and care of these patients.
